29.1.43

NEW YORK:
WILLIAM WOOD & COMPANY,
27 GREAT JONES STREET.

JOHN F. TROW & SON,
PRINTERS AND BOOKBINDERS,
205-213 *East 12th St.*
NEW YORK.

LIST OF CONTRIBUTORS TO VOL. X.

- ADAMS, Dr. F. S.
ANDREWS, Dr. W. C. C., New York.
ANGELL, Dr. E. C., New York.
ASCH, Dr. MORRIS J., New York.
ATKINS, Dr. F. H., Acting Assistant Surgeon, U. S. A.
- BACON, Dr. J. G., Saratoga, N. Y.
BARKER, Dr. FORDYCE, New York.
BAXTER, Dr. G. A., Chattanooga, Tenn.
BAYLES, Dr. GEO., New York.
BEARD, Dr. GEO. M., New York.
BENNETT, Dr. E. P., Danbury, Conn.
BENSON, Dr. D., Hoboken, N. J.
BLACK, Dr. J. R., Newark, Ohio.
BOWEN, Dr. W. S., Hartford, Conn.
BOZEMAN, Dr. N., New York.
BRADLEY, Dr. E., New York.
BRIDDON, Dr. C. K., New York.
BUCK, Dr. A. H., New York.
BULKLEY, Dr. H. D., New York.
BULL, Dr. C. S., New York.
BURRELL, Dr. F. A., New York.
BYRD, Dr. H. L., Baltimore, N. Y.
- CARO, Dr. S., New York.
CARROLL, Dr. A. L., New York.
CARSON, Dr. W., Cincinnati, Ohio.
CHAMBERLAIN, Dr. W. M., New York.
CLARK, Dr. A., New York.
CLARK, Dr. C. F., Brooklyn, N. Y.
CLEBORNE, Dr. C. J., Surgeon U. S. Navy.
COHEN, Dr. J. SOLIS, Philadelphia, Pa.
COLEMAN, Dr. J. C., Augusta, Ga.
COLLINS, Dr. D. F., New York.
COMEGYS, Dr. E. F., U. S. Army.
CROSBY, Dr. A. B., New York.
CURTIS, Dr. Edward, New York.
CURTIS, Dr. F. C., New York.
- DALTON, Dr. JOHN C., New York.
DAVIS, Dr. G. PIERREPONT, Hartford, Conn.
DAY, Dr. J. F., Fall River, Mass.
DELAFIELD, Dr. F., New York.
DIMOCK, Dr. SUSAN, Boston, Mass.
DONOR, Dr. W. J., New York.
DOUGHERTY, Dr. A. N., Newark, N. J.
DRAPER, Dr. W. H., New York.
DUNCAN, Dr. W. F., New York.
DUNSTER, Dr. E. S., Ann Arbor, Mich.
- EDWARDS, Dr. A. M., Newark, N. J.
- FEHR, Dr. J., Hoboken, N. J.
FELTON, Dr. A. D., Syracuse, N. Y.
FIELD, Dr. A. G., Des Moines, Iowa.
FINNELL, Dr. T. C., New York.
FISHER, Dr. W. R., Hoboken, N. J.
FLEISCHMANN, Dr., London, Eng.
FLINT, Dr. A., New York.
FORD, Dr. C. L., Ann Arbor, Mich.
FOWLER, Dr. G. R., Brooklyn, N. Y.
FRION, Dr. G. X., New York.
- GEDDINGS, Dr. W. H., Aiken, S. C.
GIBBES, Dr. R. W., Columbia, S. C.
GIBNEY, Dr. V. P., New York.
GILLETTE, Dr. W. R., New York.
GIRARD, Dr. A. C., U. S. Army.
GLASS, Dr. R. G., New York.
GODON, Dr. F. W., San Francisco, Cal.
GOODWILLIE, Dr. D. H., New York.
GRAY, Dr. JOHN P., Utica, N. Y.
- HADDEN, Dr. ALEX., New York.
HAMILTON, Dr. A. MCL., New York.
HARRIS, Dr. P. A., Dover, N. J.
HARVEY, Dr. P. F., U. S. Army.
HEITZMANN, Dr. C., New York.
HEWLETT, Dr. W. W., Babylon, N. Y.
HICKS, Dr. J. L., Flushing, L. I.
HOAG, Dr. W. H., Manhasset, N. Y.
HOPKINS, Dr. H. R., Buffalo, N. Y.
HOWE, Dr. JOS. W., New York.
HUDSON, Dr. E. D., New York.
HUNT, Dr. E. M., Metuchen, N. J.
HUNT, Dr. J. H., Port Jervis, N. Y.
HUNTER, Dr. A. S., New York.
HUNTINGTON, Dr. A., New York.
HURD, Dr. A., Finlay, O.
HYDE, Dr. F. E., New York.
- JACOBI, Dr. A., New York.
JANEWAY, Dr. E. G., New York.
JANEWAY, Dr. JOHN G., U. S. Army.
JOHNSON, Dr. L., New York.
JONES, Dr. E. LEE, Oakland, Cal.
- KEMP, Dr. W. H., New York.
KEYES, Dr. E. L., New York.
KNAPP, Dr. H., New York.
KULP, Dr. JOHN H., Davenport, Iowa.
- LA GARDE, Dr. L. A., U. S. Army.
LA ROE, Dr. J. G., Greenpoint, N. Y.

LEAMING, DR. JAMES R., New York.
 LEFFERTS, DR. GEO. M., New York.
 LENTE, DR. F. D., Cold Spring, N. Y.
 LOOMIS, DR. A. L., New York.
 LORING, DR. E. G., New York.
 LUSK, DR. W. T., New York.

MANN, DR. ED. C., New York.
 MASON, DR. E., New York.
 MATTISON, DR. J. B., Chester, N. J.
 MAXSON, DR. E. R., Syracuse, N. Y.
 MAYER, DR. N., Hartford, Conn.
 McELHENIE, THOMAS D., Flatbush, L. I.
 MILLER, DR. J. H., Moberly, Mo.
 MORRIS, DR. MOREAU, New York.

O'MEAGHER, DR. W., New York.
 OTIS, DR. F. N., New York.

PETERS, DR. JOHN C., New York.
 PEUGNET, DR. E., New York.
 PIFFARD, DR. H. G., New York.
 PILCHER, DR. L. S., Brooklyn, N. Y.
 PINKHAM, DR. J. G., Lynn, Mass.
 POOLEY, DR. J. H., Yonkers, N. Y.
 POST, DR. A. C., New York.
 POST, DR. GEORGE E., Beirut, Syria.
 PROUT, DR. J. S., Brooklyn, N. Y.
 PULLING, DR. E. R., New York.
 PUNYEA, DR. P. B., Imlaystown, N. J.
 PURSE, DR. B. S., Savannah, Ga.
 PUTNAM-JACOBI, DR. MARY, New York.

RANKIN, DR. FRANK E., New York.
 RIPLEY, DR. J. H., New York.
 ROBINSON, DR. BEVERLEY, New York.
 ROCKWELL, DR. A. D., New York.
 RODMAN, DR. W. B., Frankfort, Ky.
 ROOSA, DR. D. B. ST. JOHN, New York.
 ROSE, DR. A., New York.

SAGER, DR. A., Ann Arbor, Mich.
 SATTLER, DR. R., New York.
 SATTERTHWAITTE, DR. S. T., Bellaire, O.
 SATTERTHWAITTE, DR. THOMAS E., New York.
 SAYRE, MR. T. H., New York.
 SAYRE, DR. L. A., New York.
 SEGUIN, DR. E., New York.
 SHERMAN, DR. B. F., Ogdensburgh, N. Y.
 SIMMONS, DR. D. B., Yokohama, Japan.
 SIMROCK, DR. JOSEPH, New York.

SLOCUM, DR. C. E., Defiance, O.
 SMITH, DR. A. H., New York.
 SMITH, DR. J. LEWIS, New York.
 SPEAR, DR. D. D., Freeport, Me.
 STEARNS, MR. T. C., Rockford, Ill.
 STIMSON, DR. D. M., New York.
 STUDLEY, DR. H. A., New York.
 STURGIS, DR. F. R., New York.

TARBELL, DR. W. E., Kinkiang, China.
 TAYLOR, DR. C. F., New York.
 TAYLOR, DR. R. W., New York.
 THOMPSON, DR. B., New York.
 THOMSON, DR. W. H., New York.
 TRASK, DR. J. D., Astoria, N. Y.
 VOSBURG, DR. H. D., New York.

WALES, DR. P. S., U. S. Navy.
 WARD, DR. S. B., N. Y.
 WATERMAN, DR. S., New York.
 WEIR, DR. R. F., New York.
 WEST, DR. H. S., Sivas, Turkey.
 WEY, DR. W. C., Elmira, N. Y.
 WHITEHORNE, DR. H. B., Verona, N. Y.
 WATSON, DR. B. A., Jersey City, N. J.
 WATTS, DR. ROBERT, New York.
 WILSON, DR. M. A., New York.

INDEX.

A.

ABDOMEN, penetrating wound of, 21 ; gunshot wound of, 486, 556, 623, 685, 700.
Abortion, treatment of, 59, 86, 280 ; criminal, 300, 824, 860.
Academy of Medicine of Paris, change of organization of, 30.
Acute nasal catarrh, treatment of, 403.
Adams, Dr. F. S., electrolytic treatment of tumors, 719.
Addison's disease, 332.
Adulteration of drugs, 642.
Air, practical filtration of, 216.
Aitkin, Dr. W., notice of work by, 299.
Albuminuria as a symptom, 856.
Alcoholism, chronic, 475.
Alimentation and gastro-intestinal disorders of children, 394.
Alumni Association of Medical Department N. Y. University, dinner of, 154.
Amaurosis, after suppression of menses, 222.
American Medical Association, 279, 313, 343, 344, 363.
Americans, weight and height of, 288.
American Neurological Association, 410.
American Pharmaceutical Association, 641.
American Public Health Association, 796.
Ammonæmia, experiments on, 22.
Annion, hematocoele of, 683.
Anæmia, remarks on, 740, 807.
Anatomy, lessons on elementary, 621.
Anal-occlusion, case of congenital, 357.
Analysis, value of, 84.
Anchylolysis of hip, operation for, 712.
Andrews, Dr. W. C. C., dislocation at elbow, 679.
Aneurism, cases of, 478, 536, 554, 744.
Angell, Dr. E. C., inunction, 723.
Angina pectoris, 478, 808.
Ani, prolapsus, treatment of, 238.
Antiseptic paper for dressing wounds, 311.
Antrum, tumor of, 475.
Aorta, aneurism of, and laryngotomy, 45.
Apocynum cannabinum, value of, in dropsy, 460.
Apomorphin, remarks on, 23, 508, 533, 667.
Apoplexy, from miliary aneurisms, 240.
Arkansas State Medical Society, 656.
Armby, Prof. James H., death of, 832.
Army, hygiene, 617 ; Medical Staff Bill, 25, 185, 346, 519 ; losses in German, 24.
Arnica, tincture of, a dangerous application, 151.
Arnold, Dr. J. W. S., general physiology of the movements of the body, 289, 337, 497.
Arsenic poisoning, case of chronic, 64 ; eaters, 784.
Artificial respiration, an effectual method of, 406, 657.
Asch, Dr. Morris J., progress of medicine in Japan, 686.
Asphyxia, speedy method in, 519.
Asthmatic mixture, 664.
Athetosis, remarks on, 412.
Atkins, Dr. F. H., new splint for fracture of lower jaw, 266.

B.

Bacon, Dr. J. G., high temperature, 335.
Bacteria, their relations to disease, 383, 849.
Balsam copaiba, therapeutic value of, 359.
Barker, Dr. Fordyce, puerperal fever, 721.
Baths, public, in city, 463.
Baxter, Dr. G. A., inhalation of bedbug poison, 660.
Bayles, Dr. Geo., elastic ligature for funis, 583.

Beard, Dr. G. M., on electrodes, 235 ; electrolysis in tumors, 702, 817 ; spiritualism, 69.
Beard and Rockwell, review of work by, 210.
Bed-bug poison, effects of inhalation of, 660.
Bellevue, Medical Board of, 232.
Bellevue Hospital Medical College Commencement, 175.
Bellevue Hospital reports, 6, 114, 238, 268, 477, 506, 534, 661, 731, 740, 839.
Bennett, Dr. E. P., ovariectomy, 739.
Bennett, Dr. John Hughes, death of, 720, 783.
Benson, Dr. D., electrolytic treatment of tumors, 703.
Benzoic acid, remarks on, 552.
Bile, action of drugs on secretion of, 616.
Biliary calculus extracted through abdominal walls, 632.
Biometry, its relation to the practice of medicine, 481.
Bioplaxion doctrine, notes on the, 364.
Black, Dr. J. R., health measures and life insurance companies, 137.
Blackwell's Island, report of lying-in service of, 78.
Bladder, scrofulous ulceration of, 96 ; introduction of liquids into, without catheter (Zeissl's), 330 ; myoma of, 455 ; aspiration of, 767 ; injection of strychnia in, 767 ; distention of, 165.
Blake, Dr., aconite poisoning, 171 ; precocious development, 211.
Blaney, Dr. James V. Z., death of, 48.
Blood corpuscles, passage of, through blood-vessels, 604 ; diagnosis of, 116.
Blue urine, 592.
Body, movements of, 497.
Boil pest in Tripoli, 214.
Bone, bleaching of, 70 ; successful transplantation of, 272.
Bowen, Dr. W. Shaw, sympathetic disease of eye, 207.
Boylston Prize Questions, 512.
Bozeman, Dr. N., vesico-vaginal fistule, 509 ; gynecology in Vienna, 653.
Brachial plexus, injury of, 413.
Bradley, Dr. E., hypospadias, 438.
Breast, adenoma of, 171 ; cancer of, 524, 534, 614, 663 ; eczema of, 23 ; fibroma of, 523 ; puerperal diseases of, 822 ; syphilitic diseases of, 808.
Brain, cysticerci in, 40 ; repair of, 188 ; centres, two proofs of, 253 ; syphilitic, 301 ; a large, 384 ; gunshot wounds of, 550, 597 ; curious lesions of, 768.
Briddon, Dr. C. K., perforation of appendix vermiformis, 28 ; neuroma, 780 ; scrofulous testicle, 827.
Bright's disease, vomiting in, 506 ; different forms of, 743.
Bronchocele, case of, 805.
Bubenquelle, artificial, 848.
Buck, Dr. A. H., progress of otology, 386 ; otorrhœa and suicide, 287.
Buck, Dr. Gurdon, excision of head of humerus, 29 ; cicatricial contractions, 476 ; chain-saw conductor, 751.
Bulkley, Dr. L. D., urine in skin disease, 314.
Bull, Dr. C. S., iodoform in conjunctivitis, 292 ; ophthalmoscope as cerebroscope, 401.
Bunion, resection of great toe for, 21.
Burns, cicatricial contraction following, 476.
Burrall, Dr. F. A., on throat diseases, 150 ; chloroform and nitrite of amyl, 358.
Byrd, Dr. Harvey L., speedy method of asphyxia, 519.

C.

Cæsarean section successful in uterine fibroids, 320 ; in cow, 231.

- Callan, Dr. P. A., paralysis of accommodation following diphtheria, 62; otitis externa diphtheritica, 221.
- Camphor (hemæopathic), poisoning by, 239.
- Canadian pharmacy, 221.
- Cancer, remarks on, 312.
- Canine sagacity, 384.
- Carbolic acid poisoning, 759.
- Carbuncular affections, treatment of, 695.
- Cardiac action after death, 736.
- Caro, Dr. S., tapeworm treated by balsam copaiba, 826.
- Carrol, Dr. A. L., disorders of nervous system, 91.
- Carson, Dr. W., abscess of liver, 591.
- Catheter, in female pelvis, 64; broken in bladder, 860.
- Centenarian, autopsy of a, 197, 319.
- Centennial medical, 320, 761, 811.
- Cerebral convulsions, functions of, 46; vessels, syphilitic disease of, 422.
- Cerebro-spinal meningitis, 459.
- Certificates, cheapness of medical, 297.
- Cervical canal, dilators for, 655.
- Cervix uteri, new instrument for amputation of, 381.
- Charity Hospital, lying-in service at, 118.
- Chain-saw conductor, 751.
- Chamberlain, Dr. W. M., gunshot wounds of abdomen, 685; nervous disorders from genital irritation, 862.
- Chicory, danger of, in coffee, 648.
- Child killed by a rooster, 576.
- Children, department for, in Bellevue, 10; diseases of, 188; review of work on, 539; nervous diseases in, 811, 824.
- Chloral in veins, injection of, 40; by rectum, 408.
- Chloralium, 272.
- Cholera, review of work on, 538, 586; in Turkey, 576.
- Chorea, treatment of, 456, 588, 740.
- Chronic synovitis, 600.
- Chronic vomiting, 270.
- Chyluria, intermittent, 136.
- Ciliary body, white sarcoma of, 28.
- Clark, Dr. A., destruction of one lung by phthisis, 1.
- Clark, Dr. C. Frederick, new instrument for amputation of cervix, 381.
- Clavicle, treatment of fracture of, 29, 113, 392; removal of, 753.
- Clay, Dr. C., notice of work by, 227.
- Cleborne, Dr. C. J., inunction, 830.
- Cloasma uterina, tincture of iodine in, 312.
- Club-foot, simple treatment of, 782.
- Coagulation of blood, causes of, 668.
- Cohen, Dr. J. Solis, review of work by, 298.
- Gold-water treatment, researches on, 29, 709, 839; extraordinary low temperature after exposure to, 270.
- Coleman, Dr. J. C., stricture of urethra and multiple wedge, 61, 710.
- Colitis, fungoid degeneration of rectum, 131.
- Collecting Association, 215.
- College Physicians and Surgeons, Commencement, 175.
- Collins, Dr. D. F., polypus of uterus, 76; perforating ulcer of duodenum, 677.
- Comegys, Dr. E. T., electrolysis in tumors of neck, 658.
- Condie, Dr. D. F., death of, 265.
- Condylomata lata, 694.
- Conference, an international, 345.
- Conium, its use in diseases of the eye, 353, 369, 379.
- Conservative surgery, 222.
- Consumption, prevention of, 144.
- Contagious diseases of children, prevention of, 457.
- Convicts, medical treatment of, 649.
- Copper in human organism, 271.
- Cornelison, Dr. J. M., death of, 426.
- Corpus callosum, absence of, with unimpaired intelligence, 240.
- Corpus luteum and pregnancy, relative situation of, 247.
- Cough mixture, 664.
- Coventry, Dr. Chas. B., obituary of, 174.
- Coxe, Dr. C. C., inversion of uterus, 836.
- Crosby, Dr. A. B., on cystitis, 12; common sense in sick room, 593; treatment of fractures, 609; removal of seapula, 753.
- Croton chloral hydrate, remarks on, 423.
- Croton oil, poisoning by, 503.
- Croup and diphtheria, 241.
- Curare, action of, on white blood globules, 40.
- Curare, remarks on, 15.
- Curtis, Dr. Edward, conium in diseases of the eye, 353, 369.
- Curtis, Dr. F. C., diffused gangrene of lung, 148.
- Cutaneous eruption from nerve injury, 414.
- Cyclitis from inherited syphilis, 64.
- Cysticerci in brain, 40.
- Cystic tumors, sub-peritoneal, 106.
- Cystitis, treatment of, 12, 550, 734, 790.
- Cysts, seminal contents of, 24.

D.

- Dalton, Dr. J. C., functions of the cerebral convulsions, 46.
- Dangerous compound, a, 496.
- Davis, Dr. G. Pierrepont, ease of continued fever.
- Davis, Dr. N. S., notice of work by, 99; bowel affections of children, 363.
- Day, Dr. Josiah F., gunshot wound of abdomen, 557.
- Death, a certain sign of, 39, 238; maximum rate during day, 319.
- Dejections, management of, 594.
- DeLafield, Dr. E., death of, 135, 175, 215.
- DeLafield, Dr. F., typhoid fever, 75; pericarditis, 172; partial structure of intestine, 212; syphilitic brain lesions, 301; pulmonary phthisis, 338, 373; anomalous disease of stomach, 490; pneumonia, 56; typhoid fever, 774.
- Denig, Dr. R. M., croton-oil poisoning, 503.
- Dentistry, rights of, 31; galvanocautery in, 480.
- Dentition, the so-called third, 295; diseases of, 616.
- Department of Public Instruction in County of Kings, 263.
- Dermatology, report on (Journal Association), 448.
- Deserts as health resorts, 72.
- Diabetes, carbolic acid in, 759; mellitus, 238, 407.
- Diagnosis, physical, a point in, 477.
- Diaphragmatic hernia, 699.
- Diarrhea in children, 668.
- Dietetics, remarks on, 595.
- Diffraction spectra of colored fluids, 468.
- Dilatation of vessels, nerves controlling the, 253.
- Dimock, Dr. Susan, anal occlusion, 357; obituary of, 357.
- Diphtheria, remarks on, 8, 22, 30, 39, 41, 57, 62, 68, 98, 109, 156, 238, 241, 336, 391, 425, 525, 529, 575, 760, 820, 837, 841, 846, 857.
- Diplomas, American, value of, 81.
- Dipsomania and intemperance, 756.
- Disinfectant, a new, 24.
- Dislocations, apparatus for reducing, 703.
- Dog bite, case of, 568.
- Donor, Dr. W. Jerome, three cases of leprosy, 769.
- Doses, significance of, in medicine, 363.
- Doherty, Dr. A. S., death of, 71.
- Dougherty, Dr. Alex. N., india-rubber catheter, 669.
- Drainage in London, 608.
- Draper, Dr. W. H., chronic heart disease, 524.
- Dress-goods, new kind of poisonous, 604.
- Drinking-water, contaminated, and typhoid fever, 96.
- Drum membrane, method of perforating, 221.
- Dry syrup, 268.
- Duncan, Dr. W. F., apomorphia, 533.
- Dunster, Dr. E. S., homæopathy in Univ. Mich., 511.
- Duodenum, perforating ulcer of, 677.
- Dutcher, Dr. A. P., work by, 186.
- Dyes, poisonous, 456.
- Dynamometer, a new, 415.
- Dysentery, natural history of, 693.
- Dysmenorrhœa, nitrite of amyl in, 11; cause of, 68.
- Dyspepsia, pill for, 664.
- Dysuria, treatment of, 664.

E.

- Ear, insects in the, 859.
 Ear drum, description of a new, 294.
 East River Medical Association Banquet, 816.
 Eczema of breast, 23.
 Edwards, Dr. A. Mead, salicylic acid as therapeutic agent, 329.
 Elastic ligature, 67, 600.
 Elbow, dislocation of, 679, 830.
 Electricity, as substitute for gas, 192; review of work on, 210; susceptibility of, 233; in nervous diseases, 771.
 Electro-therapeutics, 121.
 Electrolytic treatment of tumors, 658, 702, 718.
 Elixirs, report on, 643.
 Embolism, case of, 491.
 Embolic aneurisms and acute cardiac aneurisms, 604.
 Embryology, review of work on, 570.
 Emphysema, traumatic, 480; treatment of, 744.
 Encephalitis, case of, 100.
 Endocarditis, remarks on, 27, 184, 476, 759.
 Endometritis and general military tuberculosis, 27.
 English medical practice, 751.
 English naval medical service, 191.
 Epimeral paralysis, 183.
 Epidemic diseases and thermometer, 669; thoracic catarrh, 424.
 Epididymitis before discharge, 691.
 Epilepsy, treatment of, 360, 376.
 Epistaxis, treatment of, 205.
 Epilepsy, treatment of, 247.
 Epithelioma of conjunctiva, 525; treated by electrolysis, 819.
 Ergot, hypodermic injection in, 39.
 Ergotin in pneumonia, 24.
 Eserine in tic, 784.
 Erysipelas, arrest of, by carbolic acid, 238; treatment of, 535.
 Esmarch's method, remarks on, 79, 372.
 Ether, death from, 352; suggestions on use of, 443.
 Eustachian tube, closure of, 448.

DESTRUCTION OF ONE LUNG BY INFLAMMATORY PHTHISIS.

By PROFESSOR ALONZO CLARK, M.D.,
NEW YORK.

THE following extraordinary case ought to be narrated, with many important details which it is now impossible to give. The patient was the son of Dr. R. C. Cone of this city, who, though a capable man, preferred, in a case so deeply involving his affections, to be guided by his professional friends. The patient was seen, therefore, from time to time, by different physicians, but by no one often enough to enable him to give a connected and satisfactory account of the symptoms. The importance of the case will, I think, justify me in laying it before the profession, notwithstanding the imperfections of this record.

It is common enough for people to say of themselves, or of another, "One lung was (or is) all gone;" but an examination contradicts this statement, with so much certainty, that I, for one, had about persuaded myself that death must occur before so much devastation could be accomplished. It is true that Dr. Morton, in his book on Consumption, published before auscultation was perfected, has reported the case of a lady who had, as he said, lost the whole of one lung, and I think part of the other; yet she was, in spite of this loss, a woman of society and enjoyed life. This and similar records (they are very few) I was disposed to believe must be set down to the account of imperfect observation. But here is really a case of phthisical or inflammatory destruction of one lung.

U. P. Cone, a little past twenty-three years of age, of good habits, rather short in stature, but otherwise well developed, having the appearance of health, on the first Sunday of April, 1871, was engaged most of the day as secretary of a very large Sunday-school, in attending public worship and a Bible class, and went to bed in usual health at ten o'clock. At half-past twelve he was awakened by an hæmoptysis. The hæmorrhage was considerable, yet not really profuse. He did not remember to have had cough, but on the 7th of January previous had some hæmoptysis while travelling. The father is a healthy man, but has lost one sister of phthisis, and his paternal grandmother had "old-fashioned consumption" (*i. e.* very chronic). On the mother's side no instance of this disease could be cited.

The hæmorrhage was not then repeated; but for the next eight days the patient kept himself very quiet and free from excitement, when he was attacked by pneumonia of the left side, beginning with a chill, attended with pain in the side, and soon with chocolate-colored or "prune-juice" expectoration. This latter was unusually profuse, amounting at one time to about half a pint in twenty-four hours; but it gradually ceased, lasting about a week in all. During this

attack considerable blood was raised with the pneumonia expectoration.

I saw him for the first time on the 15th of April. This was the fourth day of the pneumonia; he was still coughing up blood pretty freely. The question was raised, whether this pneumonia was provoked by bloody infarction from the late hæmorrhage.

April 16th. The pneumonia had solidified nearly the whole of the left lung. The pneumonic fever was high and exhausting; this and the pain in the side were considerably reduced by applying cloths wrung out of hot water to the whole anterior of the chest and abdomen, (fomentations). These and hot foot-baths relieved the pain and produced sleep.

April 20th. The rational symptoms of pneumonia, such as pain in the side and head, and the continued fever had abated; but the pulse was rapid, the pneumonic consolidation was not diminished, and râles were becoming audible over much of the lung.

May 4th. The whole left lung still solid; afternoon fever and night-sweats; severe pain renewed in left side.

May 17th. Expectoring freely, hectic continues, loss of appetite, emaciating rapidly, inflammatory and phthisical consolidation not diminished, râles everywhere in left lung.

June 16. Patient confined to bed for a little over two months. No material change of symptoms; sweats, emaciation, and consolidation as before. Although too feeble to walk, Dr. C. will to-day take his son to the country, (Green Co., N. Y.).

The effects of this change were very marked. In the country the patient soon regained his appetite; the sweats ceased, he gained strength and flesh. He improved slowly but steadily for four months, having, however, all the time, cough, and more or less of expectoration.

Nov. 18. Returned from the country, still pale and thin, has strength to walk about town for an hour at a time; no hectic or hæmorrhage, but a large cavity in the upper part of left lung, râles and dulness in all the rest of it. "Worse than would appear from the general symptoms," is a part of my note at the time.

From this time onward I saw him at long intervals, and did not record his condition again until the time of his death. In general, with the aid of his father, I can say that his health appeared to improve; that the left side of chest became more and more contracted, and the spinal column, curved in the thorax from the age of fourteen to the left, became more curved. He always had cough, more or less, with expectoration; but for eleven months before his death he was able to give the usual time and attention to a business, which he was conducting successfully, with the aid of a partner, up to the day of his fatal seizure, nine days before his death.

In this last attack he had three bleedings; one on Friday, January 24th, 1874, pretty abundant; another on the Tuesday following, more profuse than the first. Twenty minutes after this bleeding ceased, he vomited a considerable quantity of blood.

On Sunday morning the bleeding returned again, and was rapid, profuse, and fatal. The blood was discharged from the mouth and both nostrils at the same

time. He seemed to faint, reviving a little he made a few laborious gasps, and then ceased to breathe.

I saw him on Tuesday, the day of the second bleeding, but unwilling to have him make much muscular exertion, I did not make a careful examination of his chest, hoping that in a few days I could do it better, and without exciting apprehension that change of position would produce renewed hemorrhage. These accidents occurred when his non-professional friends believed that his health was almost completely restored—two years and ten months from the beginning of his illness.

A *post-mortem* examination was made on the third day after death, and I greatly regret that I was unable to attend it. I, however, saw what remained of the left lung. The examination was conducted by Dr. T. E. Satterthwaite and Dr. E. O. Cowle, very competent men, both of whom recorded what they saw. Dr. Kennedy also assisted at the examination, and confirms the reports. From these records, and from what was brought to me for inspection, the following account is compiled:

Body not much emaciated. Rigor mortis well marked.

Thorax markedly depressed and contracted on the left side. Spinal column curved markedly to the left, the highest point of convexity being at the seventh and eighth ribs. The capacity of this half of the chest was greatly diminished.

On opening the thorax the lung tissue was found occupying the left as well as the right cavity, but it was soon ascertained that the right lung, while it filled the right cavity, extended to the left, partly by emphysematous expansion, so that it appeared to fill the diminished left cavity. Turning back the extended portion of the right lung, nothing was found in the left chest but the heart, and a hard mass, three inches by two and a half, lying against the side of the spinal column, between the second and fourth ribs, firmly adherent to the posterior of the thoracic wall. In this there were no traces of the vesicular tissue of the lung, nothing like air-cells, but instead a little cheesy matter and melanotic coloring material, of the latter not a large quantity. A bronchus of large size, perhaps enlarged (bronchiectasis, Cowle), opened out of this mass, but the mass could not be inflated through it. A few remains of the smaller bronchial tubes were seen in the middle of mass, and it was covered by a continuous smooth membrane, which appeared to be the thickened pulmonary pleura, without perforation or cicatrix. Some fibrous tissue was seen amidst and around the cheesy matter and under the investing membrane (pleura). The melanotic material may have been derived from the bronchial glands, which were indistinct and partly blended with the other constituents of the mass. The lining membrane of the remaining bronchial tubes was only slightly reddened. The tubes contained no blood, and no blood-vessel was discovered which seemed to have been the source of the fatal bleeding. Dr. Cowle, however, noticed, as he thought, an ulcerated point at the outer end of the large bronchus, and thinks that the blood was discharged from that point.

The left pleuritic cavity contained no air or gas, no serous fluid, no pus.

The pleuritic membrane of this side in the inferior portions of the cavity was dotted with tuberculous granulations. Otherwise the costal and diaphragmatic pleura does not appear to be unnatural.

The heart had fallen back into the posterior curve of the ribs, and the pericardium was attached by easily broken, fibrous bands to the posterior wall of the chest,

and it had fallen downward a little, so that its apex was on the level of the sixth left rib. Consequently this poor, unbreathing residuum of the left lung was almost wholly above the heart, while both had contracted adhesions, more or less firm, to the posterior thoracic wall.

The right lung, by this retreat of the heart and great vessels, was permitted to pass over in front of them into the left cavity. This implies yielding or absorption of the mediastinal membranes. Their condition was not noticed at the autopsy.

It was chiefly by the expansion of the upper and lower lobes that the left cavity was filled. "The middle lobe," Dr. S. says, "rested on the vertebral column." Besides this great enlargement, the upper and middle lobes were studded with bright gray miliary tubercles; a few only in the lower. The upper and lower lobes were emphysematous, and the lower was congested with blood. There was no cavity, and no evidences of hemorrhage in any part of this lung.

Heart: Right ventricle was soft and flabby, otherwise healthy; walls of left thickened, having atheromatous patches on the inner surface (the same deposit in the aorta); no defect in the valves. The usual small quantity of serum in the pericardium.

Arytero-epiglottidian folds thickened (C.), a little oedematous (S.), but no ulceration of them or of the larynx.

Stomach was dilated, and about half filled with dark blood.

Liver small, slightly atrophied, tuberculous granulations along the border, hemorrhagic infarction in the lower part of the left lobe.

Mesenteric glands not materially changed.

Kidneys not much affected, capsules slightly adherent, except at a few points; normal relations preserved between the cortical and pyramidal portions; in the left, stellate arrangement of vessels on one side; right, hypostatically congested.

Spleen large and softened (softening *post-mortem*?) showing some miliary tubercles.

No other pathological changes found in the thoracic or abdominal cavities. There were no central symptoms, and the brain was not examined.

Here, then, is a case which will bear a close examination. The pathological record is entirely reliable. It was written by two of the physicians, separately, and one did not know that the other had sent his report, and yet they agree in every essential particular. Then it will be remembered that all that remained of the left lung was examined by myself, and by Dr. C., the father, who is also a competent judge.

1. The function of one lung was completely abolished, and yet the subject of this destruction had recovered from a dangerous sickness while the destructive process was going on, and enjoyed what was called good health after it was completed.

2. This destruction was the consequence of a pneumonia, which in the first week was only distinguishable from the most common form of that disease by the facts that it occurred a week or eight days after a pulmonary hemorrhage, and that it was attended by a free expectoration of blood.

3. This pneumonia, however, did not resolve—never was resolved by either of the usual methods, vesicular softening and expectoration, or vesicular softening and absorption—but after six or eight weeks began to break down, with a sort of ulcerative action that destroyed all the different lung tissues at the same time; and seven months from the beginning of the pneumonia this process had excavated all the upper portion of the lung, leaving the middle and inferior portions, so far as can be judged, to the five or six following months.

4. The proper pneumonic symptoms were followed, after an interval of about two weeks, by symptoms of phthisis, which became extreme in two or three weeks from their commencement, having, however, a duration of only a few weeks, with the exception of cough and expectoration.

5. The tubercles found after death, were they the offspring of "the cheesy degeneration" of the left lung, or do they belong to the diathesis which caused the hæmoptysis that preceded the pneumonia?

6. It would hardly seem possible that the pneumonia and after-obliteration of the lung should not have obstructed the circulation from the right heart, and set back the venous blood upon the large viscera of the abdomen. Yet there was no hypertrophy of the right ventricle; and while there was infarction to a limited extent in the left lobe of the liver, and enlargement of the spleen, the liver is described as smaller than natural. The size of the pulmonary arteries, right and left, is not referred to; but it is fair, under the circumstances, to infer that the right branch was materially enlarged, and the right heart in this manner relieved.

7. In rapid and overwhelming hæmoptysis it is common to find that portions of the blood have been drawn into the lung, producing spots of pulmonary apoplexy. In this case nothing of the sort occurred, but the blood not actually discharged from the mouth seems to have found its way into the stomach.

Original Lectures.

ON CARDIAC HYPERTROPHY.

By ALFRED L. LOOMIS, M.D.,

PROF. PRACT. MED. AND PATH. IN MED. DEPT. NEW YORK UNIVERSITY.
(Photographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—At our last two clinics in the hospital I brought before you a number of patients with more or less extensive cardiac hypertrophy, the hypertrophy in no two cases depending upon the same cause. While the clinical aspect of this affection is fresh in your minds, I will consider somewhat in detail the prominent points in its history.

By the term cardiac hypertrophy is meant thickening of the walls of the heart by an increase in their muscular tissue. This muscular increase may be confined to one portion of the heart, or it may involve the walls of both auricles and ventricles. There are three recognized forms of cardiac hypertrophy.

First,—*Simple Hypertrophy*.—In this form there is an increase in the thickness of the walls of the heart, but the capacity of the cavities is not increased. Simple hypertrophy is usually confined to the left ventricle, and is most frequently met with in connection with chronic Bright's disease and chronic alcoholism.

Second,—*Eccentric Hypertrophy*.—In this form there is thickening of the walls of the heart, with increase in the capacity of its cavities. This form is most commonly met with, or occurs as the result of some valvular lesion.

Third,—*Concentric Hypertrophy*.—In this form of cardiac hypertrophy there is claimed to be thickening of the walls of the heart, with diminution in the size of the cavities. Some observers deny the occurrence of this form of hypertrophy, and claim that the diminution in the capacity of the cavities is only apparent; that it is the result of violent ventricular contraction just prior to death. I have never seen an example of this form of hypertrophy, and mention

it only for the reason that your attention is called to it in most of your text-books.

Morbid Anatomy.—The anatomical changes which take place in cardiac hypertrophy vary according to its seat, and somewhat according to the character of the hypertrophy. In eccentric hypertrophy there will always be an increase in the size of the papillary muscles, and the septum will be thickened, which does not necessarily occur in connection with simple hypertrophy. It is often difficult, even after death, to determine the existence of a moderate degree of cardiac hypertrophy, while extensive hypertrophy is very readily recognized.

When cardiac hypertrophy exists, the first thing to be noticed is a change in the shape of the heart, and that change will correspond to the seat of the hypertrophy. If the hypertrophy is confined to the left ventricle, either simple or eccentric, the heart will assume a more than usual pyriform shape, and become elongated; the right ventricle seems to be a mere appendage to the left.

On the other hand, hypertrophy of the right ventricle increases the horizontal measurement of the organ, and gives it a more oval shape. If all the cavities of the heart are increased in capacity, and their walls hypertrophied, the whole heart will be increased in size, but the change will be most marked in its horizontal direction, and the organ will assume a globular shape.

In connection with any form of hypertrophy it will be noticed that the cardiac walls are stiff, so that when the cavities are opened and the blood has been removed from them, they do not collapse. The color of the muscular tissue is redder than that of normal cardiac muscle. Cardiac hypertrophy is really a hyperplasia; there is an increase in the number of the muscular fibres, differing in no way in their anatomical structure from the normal heart muscular fibre; it is simply an abnormal growth of the normal tissue of the heart. There may be occasionally an increase in the size of the muscular fibres, but the hypertrophy mostly consists in an increase in their number. There is no well-defined limit to cardiac hypertrophy. The heart may reach such a degree of enlargement as to weigh forty ounces more than when in its normal state. After the hypertrophy reaches a certain point, secondary cardiac dilatation is liable to develop. Preceding and accompanying this form of dilatation there is fatty degeneration, which shows itself first in the more recently formed muscular fibres. An increase in the number or size of the muscular fibres of the heart-walls causes a corresponding increase in the power of the heart.

In general terms, cardiac hypertrophy is the result of over-work; for some reason the cardiac walls are called upon to perform more than their normal amount of labor, and an increase in the number of the muscular fibres necessarily follows an increase in the labor to be performed by muscular walls.

The walls of a hypertrophied heart vary in thickness, according to the cause of the hypertrophy. The walls of the left ventricle may become an inch and a half, or even two inches in thickness, while those of the right ventricle rarely reach an inch in thickness. The heavier a heart becomes, the deeper does it lie in the thoracic cavity, the diaphragm is pushed down, and the heart inclines more to the left of the thorax.

Etiology.—Whenever the function of the heart is permanently or repeatedly overtaxed, or when the resistance which it should normally encounter is increased, hypertrophy of its walls is the result. The modes by which it is directly induced are as follows:

First,—*Dilatation of the Cavities of the Heart*.—Under

certain circumstances, most of which have already been referred to, dilatation of one or all of the cavities of the heart takes place during its diastole, the capacity of the cavities is consequently increased, and they receive more than their normal quantity of blood. A certain degree of force is required to discharge the normal quantity of blood from the heart cavities; if there is more than the normal quantity, a greater than the normal degree of force is required to expel it. This demand for increased heart-power is supplied by an increase of muscular fibres in the heart walls, the hypertrophy is developed in proportion to the increase of force required to properly perform the increased amount of labor. This is the cause of all those conditions of cardiac hypertrophy found in connection with valvular lesions. Under these circumstances the hypertrophy is always eccentric, and is not due so much to the valvular lesions as to the dilatation of the heart cavities, which occurs as the result of the valvular lesions. The order is, first, dilatation, then hypertrophy, to compensate for the dilatation. The dilatation is developed during the cardiac diastole; the hypertrophy during the cardiac systole.

Second.—Mechanical Obstruction.—There is a long list of mechanical obstructions which will give rise to cardiac hypertrophy.

The first which I shall name are those which originate in the heart. Aortic stenosis gives rise to hypertrophy of the left ventricle; mitral stenosis to hypertrophy of the left auricle; pulmonic disease to hypertrophy of the right ventricle; tricuspid stenosis to hypertrophy of the right auricle. The other valvular lesions, which are attended by cardiac hypertrophy, first cause dilatation of the heart cavities, and the hypertrophy, as already shown, develops as the result of the dilatation.

Again, in this list of mechanical causes are included all the diseases of the arteries which give rise to cardiac hypertrophy. The walls of the large arteries may lose their elasticity from atheromatous degeneration, or they may be constricted or dilated, and thus offer obstruction to the blood current. An aneurismal tumor may have developed sufficiently to obstruct the current of blood, or some tumor may press upon and diminish the calibre of the aorta; under such circumstances a more than normal amount of work will be imposed upon the left ventricle, and simple cardiac hypertrophy will be developed as the result.

Again, obstruction to the pulmonary circulation will give rise to hypertrophy of the walls of the right ventricle; in many instances dilatation will occur prior to the hypertrophy, but in quite a large number of cases direct hypertrophy of the right ventricular walls will occur as the result of obstruction to the pulmonary circulation. Such obstruction may be developed in connection with pulmonary emphysema, chronic pleurisy, and other chronic diseases which affect the circulation of blood through the lungs. It does not ordinarily occur in pulmonary phthisis, for the reason that the pulmonary circulation is not obstructed to any great extent by the phthisical changes.

Again, hypertrophy of the left ventricle occurs as the result of interference with the general capillary circulation. Examples of this are met with in cases of chronic Bright's disease, especially when the kidneys have undergone atrophy. Simple hypertrophy of the cardiac walls is one of the most constant attendants of this stage of kidney disease.

In chronic alcoholism rheumatic hyperinosis, or any other condition which interferes with the systemic capillary circulation, more or less extensive simple cardiac hypertrophy of the left ventricle is developed.

Any thing which increases, for any length of time, the rapidity and force of the heart's contraction, may produce cardiac hypertrophy. Among this class of causes may be included excessive and prolonged muscular exercise. Pericarditis is not unfrequently a cause of cardiac hypertrophy, either by inducing softening and dilatation of the ventricles, or by the obstruction which is offered to the heart's action by the adhesions between the two surfaces, which result from the inflammatory processes. You will occasionally meet with cases where no cause can be found for the cardiac hypertrophy.

In detailing the causes of hypertrophy of the walls of the heart, I have confined myself to the primary hypertrophy. In order that you may not be misled by these statements, it is well for you to remember that hypertrophy of the walls of one cavity is soon followed by increase in the walls of other cavities. For instance, hypertrophy of the left ventricle, after a time, leads to hypertrophy of the right ventricle, and hypertrophy of the right ventricle leads to that of the right auricle, and secondarily to that of the left ventricle. Any cause which increases the rapidity and force of the heart's actions, if long continued, will lead to cardiac hypertrophy.

Symptoms.—It is exceedingly difficult to describe the phenomena which attend cardiac hypertrophy, for they almost always depend upon, or are associated with, some valvular lesion or arterial change, or some cause of capillary obstruction, all of which modify, or to a greater or less extent obscure the phenomena, which attend cardiac hypertrophy. Total eccentric hypertrophy usually cannot be detected, except by a physical exploration of the chest. There are, however, certain objective symptoms which are important and which will aid in its diagnosis. The direct effect of general hypertrophy of the heart is to cause an abnormal fulness of the arteries, and a lack of blood in the veins. The pulse is full and strong, the face is easily flushed, the eyes somewhat prominent and brilliant, and there is carotid pulsation. The respiration is not usually disturbed until the heart becomes so increased in size as to give rise to pressure upon the adjacent lung tissue and upon the diaphragm; then the patient will have a sense of fulness about the chest, and with that sense of fulness there will be more or less uneasiness in the epigastrium, and the stomach digestion may be more or less interfered with. If dyspnoea is present, it is due to the pressure of the enlarged heart, rather than to any change in the lung tissue. This class of patients are very apt to complain of cardiac palpitation when excited, especially if the hypertrophy is insufficient to completely overcome the obstruction. In almost all cases there is some cerebral hyperaemia, consequently you will find in persons who are the subjects of eccentric cardiac hypertrophy that alcoholic stimulants, nervous excitement, and active physical exercise cause headache, vertigo, ringing in the ears, and bright spots or flashes before the eyes. In such persons cerebral apoplexy may at any time occur. In fact, the majority of the cerebral apoplexies which occur in young subjects are associated with cardiac hypertrophy. It is now well established that there is close connection between the development of atheroma of the arteries in certain instances and cardiac hypertrophy. Some observers claim that the cardiac hypertrophy is secondary to the arterial changes; but it is a fact of every-day observation that cardiac hypertrophy from valvular changes may give rise to atheromatous changes in the arteries, for reasons which have already been fully considered in connection with the history of valvular diseases. The steps of the change

are, first, cardiac hypertrophy; second, endocarditis; and lastly, atheroma.

Thus it will be seen that although the general symptoms of cardiac hypertrophy are not at all diagnostic, yet, when considered in connection with its physical signs, the diagnosis is generally very easily made.

Physical Signs.—The physical signs of cardiac hypertrophy will vary with the seat and extent of the hypertrophy. When the hypertrophy is *general*, upon *inspection* you will notice that although the heart's action is regular, there is an increased area of visible impulse; there is a visible motion with each cardiac pulsation over and even beyond the entire precordial space. In children there is often a visible prominence of the precordial spaces.

On *palpation* the area greatly exceeds that within which the normal apex beat is felt, and the impulse has a heaving, lifting character. Usually the apex beat of a healthy heart is perceptible only over a space corresponding to one or two intercostal spaces, while the shock of a hypertrophied heart may be perceptible over the whole precordial space; and in cases of extensive hypertrophy the head of the listener is often lifted by the shock. When the right ventricle is the seat of the hypertrophy, the thoracic wall between the apex and the lower edge of the sternum, or even the sternum itself, is shaken, causing a strong epigastric impulse. When the left ventricle is the seat of the hypertrophy, the apex beat is felt farther to the left than natural, sometimes three inches below, and three or four inches to the left of the normal position. In total eccentric hypertrophy the cardiac impulse is different both longitudinally and transversely. The apex beat, in hypertrophy of the right ventricle, will be carried to the left and upward, whereas in hypertrophy of the left ventricle the apex beat will be carried to the left and downward.

On *percussion*, when general cardiac hypertrophy is present, the normal area of cardiac percussion dulness, both deep-seated and superficial, will be increased to the right or left, or downward. The dulness does not increase upward, except in rare instances, when the auricles are not only hypertrophied but dilated. If the hypertrophy is confined to the right ventricle, the area of dulness may extend considerably to the right of the sternum; while, if the hypertrophy is confined to the left side of the heart, the area of dulness may extend considerably beyond the left nipple. It is by these signs that you decide whether right or left side hypertrophy exists. The area of superficial cardiac dulness will correspond to that portion of the heart which is uncovered by lung tissue. When eccentric hypertrophy of the left ventricle is present, the superficial area of dulness will be increased to the left; when the same condition of hypertrophy is present in the right ventricle, the superficial area of dulness will be increased to the right. Usually it is not necessary to resort to percussion in order to determine if cardiac hypertrophy is present. By palpation you readily determine the position and character of the apex beat; if you find it far to the left of its normal position, and of a heaving, lifting character, you may be certain that there is hypertrophy of the left ventricle.

On *auscultation* you will notice that the first sound of the heart, if not accompanied by a murmur, is dull, muffled, and prolonged; in some cases greatly increased in intensity. If the hypertrophy is confined to the left ventricle, the second sound heard over the aortic orifice is much increased in intensity; if the right ventricle is hypertrophied, the second sound over the pulmonic orifice will be increased in intensity. I have noticed in extensive hypertrophy that often both sounds of the

heart have a kind of metallic ring which is unnatural. You will also find that there is a diminution or an entire absence of the respiratory murmur over the normal precordial region. In this connection it is necessary to call your attention to the fact, that not unfrequently you will find, when extensive pulmonary emphysema exists, although the heart may be very much increased in size, the increase in the volume of the lungs so shut over the heart, that, notwithstanding its hypertrophied condition, the apex beat will not be very much increased in force, and the heart sounds will be diminished rather than increased in intensity. It may, however, be assumed that when extensive pulmonary emphysema is present, and is attended by venous pulsation in the neck, that there is hypertrophy and dilatation of the right ventricle, and perhaps you may be able to develop an abnormal area of cardiac dulness on the right side.

Differential Diagnosis.—The diagnosis of cardiac hypertrophy is not usually very difficult.

The distinctive points of eccentric hypertrophy of the left ventricle—the most frequent form of cardiac enlargement—are a full, strong pulse; carotid pulsation; flushed countenance; prominent and brilliant eyes; an abnormally forcible apex beat, which is visible over an unnatural area, more marked below and to the left of the normal position of the apex beat; an increased area of cardiac dulness, also to the left and downward; increase in the intensity of the heart sounds, especially of the second sound over the aortic orifice.

The distinctive points in the diagnosis of eccentric hypertrophy of the right ventricle, next in order of frequency, are, a forcible heart's action, noticeable along the sternum and the left lobe of the liver, the apex beat being carried to the left and upward rather than downward—the cardiac impulse reaches nearer to the median line than normal, giving rise to more or less marked epigastric impulse; an increased area of cardiac dulness to the right, increased intensity of the pulmonic sounds, and more than normal intensity of the first sound of the heart near the median line; the two latter are the most reliable signs in the diagnosis of hypertrophy of the right ventricle. The diagnostic signs of total eccentric cardiac hypertrophy are similar to those of eccentric hypertrophy of the left ventricle, except that the area of cardiac dulness is increased in all directions, and all the heart sounds are more intense than normal. In the differential diagnosis of enlargements of the heart you are liable to confound hypertrophy with other enlargements of the same organ. *First*, with cardiac dilatation; *second*, with thoracic aneurism; *third*, with thoracic, aneurismal, and mediastinal tumors; *fourth*, with consolidation of lung tissues which may surround the heart. Under certain circumstances pleuritic effusion may be confounded with cardiac hypertrophy.

But the points of its differential diagnosis can better be considered in connection with cardiac dilatation. I will therefore defer its further consideration until we have completed the study of the latter affection.

Prognosis.—Cardiac hypertrophy admits of a more favorable prognosis than any other cardiac affection. In almost all instances it is compensatory, and the urgent symptoms which give rise to its development are relieved, and life is prolonged. Simple cardiac hypertrophy, unless the result of aortic stenosis, may exist for years without the occurrence of any dangerous or very troublesome symptoms.

Slight hypertrophy of the left ventricle is very common in those who have led an active life, and have been compelled to perform violent and prolonged physical labor: the hypertrophy is no more than is

required to maintain an equilibrium in the circulation, and in no way interferes with duration of life. The patient should not be made aware of the presence of such hypertrophy, for it seems to have an unfavorable significance, and a knowledge of the fact may greatly disturb the patient. When, however, cardiac hypertrophy is present, in which there is not only hypertrophy, but degeneration of the hypertrophied walls, the result of imperfect nutrition, after the manner already described, the prognosis is very unfavorable.

The prognosis in hypertrophy of the right ventricle is by no means as favorable as in hypertrophy of the left side of the heart; because it must inevitably be accompanied by considerable pulmonary obstruction, and consequently is rapidly progressive. It is hardly necessary for me to say that the prognosis in any case of cardiac hypertrophy depends upon the cause of the hypertrophy. The reason for this is apparent. We now come to the subject of treatment.

Treatment.—Although we cannot expect by any mode of treatment to cure cardiac hypertrophy, still much can be done to arrest its development, by removing the causes which produce it, or by rendering them inoperative. Patients with cardiac hypertrophy must avoid alcoholic stimulants.

They also should avoid immoderate eating, active and prolonged physical exercise, and mental excitement; these are things especially to be avoided. All those conditions which interfere with the general circulation, if possible, must be removed. This embraces interference with the abdominal circulation, as well as the pulmonary and systemic. Straining at stool and constipation should be avoided by daily keeping the bowels freely moved. This condition of the bowels should be maintained chiefly by habits of life, and regulation of diet, cathartics being resorted to only in exceptional cases. Any symptoms of cerebral oppression must be immediately relieved by those means which diminish the force of the heart's action. When the pulse is full and strong, and there are evidences of cerebral hyperemia, it has been the practice of some to bleed the patient; but this treatment is contraindicated, for the presence of anemia greatly aggravates the dangers arising from cardiac hypertrophy. The symptoms must be very urgent to warrant resorting to it. Of all the remedial agents which diminish the force of the heart's action I have found aconite the best. When given in full doses it is more reliable than any other means I have employed. You may administer every three or four hours from two to three drops of Fleming's tincture of the root. No drug that I have used so fully and promptly relieves the vertigo and other painful sensations that attend cardiac hypertrophy. When the dilatation of the cavities exceeds the hypertrophy of the cardiac walls, aconite does harm.

The use of *digitalis* is *contra-indicated*, unless there is degeneration of the hypertrophied cardiac walls; for its action is to increase rather than diminish the force of the heart's action. Unquestionably it is one of our most reliable agents in those diseases of the heart in which the heart's action is enfeebled; but it should never be given in those cases where the power of the heart's action is increased. I shall tell you hereafter to administer *digitalis* in chronic Bright's disease, although hypertrophy of the left ventricle is one of its most constant attendants; but I advise its administration for the relief of the kidneys, which when relieved give secondary relief to the hypertrophied heart. Besides, in many cases of Bright's disease, the heart, although hypertrophied, is not able to overcome the obstruction to the circulation in the

small arteries and capillary vessels, and the tonic effect of the *digitalis* raises the heart-power to the point where the obstruction is overcome, and the equalization of the circulation established.

Reports of Hospitals.

BELLEVUE HOSPITAL.

REPORTS OF PRACTICE, AND PECULIARITIES OF TREATMENT.

DEPRESSION OF OUTER TABLE OF SKULL, AND FRACTURE OF THE VITREOUS TABLE—A POINT IN DIAGNOSIS.

A boy, twelve years of age, had received a blow over the right palpebral region, which had knocked him down and produced slight concussion of the brain. From the concussion he was fast recovering. The eyelids and tissues about the eye were badly swollen and of a dusky color.

Upon examination it was found that the outer table of the skull was depressed slightly, and the depression extended over considerable space. The case was left to itself, with the belief that such practice could be adopted with safety. The reason was, that the depression was only slight, and extended over considerable space, and that there were no special evidences of brain complication. Trephining in such cases is not necessary. If, on the other hand, the depression extended over only a small space, such, for example as that produced by a pointed body impinging against the skull, even though the wound may seem insignificant and brain symptoms be entirely absent, it is well to trephine, for the reason that there is a great chance you will find spiculae of bone depressed in such a manner as inevitably to give subsequent trouble if permitted to remain.

Forty-eight hours after admission the boy was dead. Symptoms of meningeal inflammation were rapidly developed, and post-mortem determined that they were excited by spiculae of depressed bone. The case well illustrated the great difficulty, in certain cases, in determining *positively* the best thing to be done for such patients.

STONE IN THE BLADDER, CYSTITIS AND CYSTOTOMY.

The cystitis had long preceded the development of symptoms of stone in the bladder. Patient fifty-four years of age. The points of interest were:

- (1.) Cystitis was no hindrance to the formation of calculus.
- (2.) Cystitis did not countermand the operation of lithotomy.

Lithotomy was performed, and the patient did remarkably well.

HOW TO ESCAPE A HIGH AMPUTATION OF THE THIGH WHEN THE KNEE IS SEVERELY INJURED.

The case was sufficiently interesting to warrant a somewhat extended record. A man, forty years of age, healthy and strong, had received a very severe injury, producing a compound fracture of the bones of the leg, affecting the muscles above and below the knee-joint, nearly tearing away the patella, and extensively destroying the vitality of the skin. All the tissues were enormously swollen, and the swelling extended to a point about half way up the thigh. The first suggestion was to amputate through some tissues at a point just above the injury. That would bring the operation well towards the upper third of the thigh. In the face of that suggestion was the fact—

incontestably proven by statistics—that amputation at this high point in the thigh, in cases of compound fracture, was almost equivalent, *in the adult*, to a fatal operation.

* A consultation was held, and it was determined to go directly through the damaged tissues and amputate at the knee-joint. The object in so doing was to save the man from the shock of the high operation under these circumstances. It was known perfectly well that the tissues above the point, when the operation was performed, would slough, and perhaps extensively; but it was believed that the lesser shock of the operation at the knee-joint, although followed by sloughing, would be less jeopardizing to the life of the patient than the high operation would be under the same circumstances. As anticipated, the tissues did slough, and quite extensively; the flaps were undermined, and the whole stump was one mass of granulations without purpose, and through these granulations and sloughing tissues the extremity of the femur protruded.

At this time, when the granulations in the wound were well commenced, the *secondary* operation was performed. The femur was removed within the lower third, the flaps brought together to cover the end of the bone, and left to unite by secondary adhesions. The shock of the secondary operation was almost nothing. Patients bear these secondary operations well, and that was regarded as a point of great importance in the consideration of the case.

The result of the method of procedure was, escape of dangers attending the high operation, circumventing them by primary amputation at the knee-joint; secondary amputation, when the patient was in far better condition to bear the shock of the operation. The operation, also, could be performed and be attended with but little shock.

THE TREATMENT OF TETANUS.—The same patient had tetanus also, but the disease extended no farther than trismus. He is now far advanced towards recovery. The treatment for the trismus was a combination of remedies to meet two indications. The disease is characterized by pain and spasm, therefore opium gr. i. and assafœtida gr. ij. were given in combination every two hours and continued.

The visiting surgeon remarked, that about one-third of the ordinary cases may be saved by this treatment, and that he had no confidence in specific remedies for this disease.

THE DIFFICULTY OF DECIDING THE EXISTENCE OF SHORTENING AFTER FRACTURE.—Recovery had been made, it was said, *without* shortening. A single case, however, proves nothing with regard to the merits of the treatment. There was one remark dropped with reference to the reason why plaster-of-Paris is not always the best dressing that can be used in the treatment of this class of fractures, as follows: The theory is, that the method claims its recognition upon the ground that it has the power to maintain an exact co-operation of the fractured extremities of the bone. If the limb were marble or wood, the possession of such power can be very easily appreciated; but the limb is not a marble or wooden limb, and it will waste both on account of the pressure from the bandage itself, and also the atrophy which always follows from want of exercise. The result is, the limb shortens by all the influence which the muscles exert when the support is removed.

The first measurement of the limbs under consideration made one-fourth of an inch difference in length; the *second* measurement, however, made nearly half an inch difference in length between the two limbs,

and it was concluded not to make any more measurements.

Practically there was no shortening. Cases in which there is absolutely no shortening are extremely rare.

Progress of Medical Science.

NUX VOMICA IN NERVOUS DISEASES.—Dr. Stefani, contrary to the generally received opinion, considers nux vomica to have a depressing effect on the ganglionic system. He therefore employs the alcoholic extract in all acute and severe hyperæsthenic maladies, as well as in chronic cases, whenever any nervous symptoms connected with the ganglionic or cerebro-spinal system are manifested. In acute diseases the remedy is rapidly beneficial, and in proportion to the size of the dose. The tolerance of the remedy is greater in the chronic affections of the ganglionic system than in those of the cerebro-spinal. Intolerance of the drug may be recognized by the rapidity of its action and the great sympathy between the two nervous systems, and by the extensive range of the spinal symptoms. The intolerance is indicated in these last by the stiffness of the lower jaw and of the tongue, with some subultus in the lower limbs or in all the body.

The muscular force is depressed by the remedy, if this has been stimulated by the hyperæsthenia; it also stimulates it when the same cause has produced apparent depression. It lowers the pulse when hard and vibrating, and raises it when small and weak. Both the pulse and the temperature are regulated when they vary several times a day. It relieves ardent thirst and obstinate costiveness; arrests diarrhœa and spontaneous hemorrhage; relieves hemorrhoids and relaxes spasms; removes neuralgic, pleuritic, and rheumatic pains. It calms delirium and removes morbid wakefulness or awakes the patient from morbid sleep; promotes perspiration when deficient and arrests it when profuse, whenever any of the above symptoms are the result of nerve trouble. Even in such cases ordinary remedies should first be tried. When the nux vomica is resorted to, use it boldly, so as to be sure how much is to be ascribed to the disease and how much to the remedy. Continue it a day or so to prevent a relapse.

Dr. Stefani gives adult patients with chronic diseases from five to ten centigrammes of the alcoholic extract. In grave cases the dose may be raised to from fourteen to thirty centigrammes in the twenty-four hours. He combines it with an equal quantity of the extract of rhis radicans and four or five times as much extract of hyoseyamus.—*Lo Sperimentale*. May and June, 1874.

POSSIBILITY OF DIAGNOSING SYPHILIS BY CALOMEL INJECTIONS.—Dr. Steffanini relates the case of a girl thirteen years of age, who, without having any previous illness, began to complain of sore throat. Astringent gargles did no good, the voice becoming daily more nasal and raw, and liquids were regurgitated from the mouth through the nose. When the patient came to the hospital, it was found on examination that the velum was jagged at its margins and the uvula was destroyed, leaving nothing but two small excrescences covered with sound mucous membrane. The tonsils were slightly swollen and ulcerated, and the glands about the neck enlarged. Specific disease was suspected, but the suspicion was not strengthened by further examination of the parents or child. Ordinary remedies were again resorted to without benefit.

After nearly two weeks a subcutaneous injection of calomel was made in the outer side of the left arm. The dose was about a half grain suspended in about fifteen minims of glycerine. In two days the throat was much better. A second injection was made two weeks later, the patient steadily improving, except that she had a slight irido-cyclitis. Two further injections were made at about the same intervals, after which the patient was entirely cured.—*Giorn. Ital. del Malat. Ven.*, 2, 1874.

FOREIGN BODIES IN THE ŒSOPHAGUS.—At a meeting of the Société de Chirurgie on the 7th of October last, Duplay related the case of a man who came to the hospital, stating that he had swallowed a bone. Efforts were made to extract it, but without avail, and finally as the patient could take liquid food very well, and a bougie of moderate size could be passed into the stomach without difficulty, it was believed that the foreign body was no longer in the œsophagus. On the sixth day after admission a sharp attack of bronchitis set in, and was followed by broncho-pneumonia and pleurisy, and the patient died on the fourth day of this last attack. At the post-mortem examination it was found that a triangular piece of bone had lodged in the posterior wall of the œsophagus, opposite the fourth dorsal vertebra; one angle of the bone was turned upwards, another to the right, and another to the left. It was regretted that the instrument of Collin was not at hand, as the resonator with which it is provided would have apprised him of the foreign body, and œsophagotomy might at once have been performed. Houel related a case in which an individual swallowed a twenty-franc piece: fruitless efforts were made to extract it and the patient died of hemorrhage on the 8th or 10th day. The œsophagus was permeable for its whole length, but it had been perforated and the aorta had been eroded, whence the fatal hemorrhage. Trélat called attention to the existence of the constriction which is found normally at the junctions of the upper and middle third; he also spoke of the difficulty in reaching the anterior wall, and that it was necessary to have the patient bend the neck strongly backwards, which is only possible in young persons; he stated that operations to be successful should be performed at once, as on the following day the foreign body may be encysted in the swollen mucous membrane. Emetics should be discarded as dangerous; he prepared himself for cases of this kind by keeping on hand a full assortment of bougies with calibres reaching as high as 15 millimetres.—*Allg. Wien. Med. Ztg.*, 44, 1874.

TREATMENT OF DIPHTHERIA AND SCARLET FEVER.—In a late number of the "Jahrbuch f. Kinderhülfe." Meyer describes his treatment of diphtheria with ice. Even when the children are very young and with infants under one year, he has them fed with small bits of ice, which are allowed to dissolve in the throat. In addition, he pours ice water on the tongue every few minutes. The ice should be very clean, and the artificial kind is the best. In very severe cases the external use of cold in the form of ice cravats is very suitable. It is also stated that under this treatment the fever generally yields, the membranes are thrown off, general infection of the system does not follow, and the disease rarely extends into the larynx. He employed cool baths in diphtheria to moderate excessive fever in one case, but in scarlet fever he found it generally of great advantage. When, however, the temperature exceeds 102.5° Fahr., tepid baths, varying between 71° and 81° Fahr., are to be used, and they may have as low a temperature as 64° Fahr. After

the bath the temperature of the body remains reduced for a number of hours.—*Allg. Wien. Med. Ztg.*, 44, 1874.

LYMPHATIC TUMORS OF THE FACE.—Dr. Leoni describes a remarkable sort of affection that occurred in his own person, and the nature of which he can only suspect. One day his right upper lip commenced to swell until it became a tumor of considerable size. He could assign no cause for it, for he had received no injury there, nor had there been previous trouble of any kind. The swelling was not painful, but gave the sensation of great tension, as if it was in a state of erection. At the end of two hours it had disappeared as suddenly as it came. Subsequently, similar swellings occurred on two occasions, once in the same place, and once in the lower lip and chin, lasting in this last case from three to four hours. He tried in vain to reduce them by pressure and manipulation, and finally introduced an exploring needle through the mucous membrane of the mouth, thinking to evacuate the contents, if they were fluid. Nothing, however, escaped. Leoni thought there was no evidence to show that the tumors contained blood. It seemed more likely that they were lymphatic in character, and produced by some obstruction in the course of the lymphatic vessels. We had observed the same affection, in a less degree, in a young woman, at the commencement of her menstrual epoch.—*Nord. Med. Ark.*, vi., 2, 1874.

THE HYDRATE OF CHLORAL TO ARREST PUTREFACTION AND FERMENTATION.—The experiments of Dujardin, Beaumetz, and Hirne show that the hydrate has a certain power in arresting fermentation, for the formation of lactic acid in milk was prevented by it and when only a one-per-cent. solution was used. The decomposition of urine was likewise prevented by a weak solution, so that at the end of a month it had undergone no change. As a local application, the writers found that it was excellent for foul wounds, gangrene of the skin or mucous membranes, cancerous sores, phagedenic chancres, and the like. They found in all cases that it produced no pain, destroyed the fetid odor, cleansed the surface, and promoted cicatrization. It seemed, therefore, specially adapted for a local application in carcinoma uteri. Judging from its power of preventing the decomposition of urine, they recommend it as an injection (one per cent.) in those diseases of the bladder that are accompanied by rapid decomposition of the urine.—*L'Union Médicale*, 1873. *Rundschau*.

SURGEON EUGENE H. ABADIE.—Surgeon Eugene H. Abadie of the United States Army, died recently in St. Louis. He was a native of France, and entered the medical service of the United States as assistant surgeon in 1836, being appointed from Pennsylvania. He received his commission as surgeon in 1853, and was honored with the rank of colonel by brevet, near the close of the war, in March, 1865. His period of active service was exceeded only by that of two other officers in the Medical Department.

PARMLY.—At his residence, 19 West Thirty-eighth street, Sunday, December 13, suddenly, of pneumonia. Dr. Eleazar Parmly, aged 77 years and 9 months.

SMITH.—At his residence, Mount Vernon, Ohio, December 15, Dr. Harvey W. Smith, formerly of this city, in the 49th year of his age.

WRIGHT.—Suddenly, in Brooklyn, N. Y., December 10, 1874, Albert Wright, M.D., aged 70 years and 8 months.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 2, 1875.

THE WEEKLY MEDICAL RECORD.

WITH the present number we commence the weekly issue of THE MEDICAL RECORD. In so doing we trust we shall be meeting a want long felt not only in this city but elsewhere. When we consider the number of medical journals published in this city we have reason to congratulate ourselves that, as a profession, we are not far behind our European brethren. Before the war, we had in reality but one journal which deserved the name, and this expired with the *American Medical Times*, into which it had been merged. Since that time, at varying intervals, there have been established three monthlies, the New York Medical Journal, the American Chemist, and the Psychological and Medico-Legal Journal; one semi-annual, The Archives of Electrology and Neurology; three quarterlies, the New Remedies, The American Journal of Syphilography and Dermatology, and the Archives of Dermatology; and one semi-monthly, THE MEDICAL RECORD. All of these are well sustained by contributions, and have been reasonably successful. This certainly speaks well for medical journalism in this city, and is in strange contrast with the state of affairs fifteen years ago, when but one periodical could be supported, and that only by dint of much begging for money, and still more begging for communications. Professional sentiment has so far changed in favor of the necessity of medical journalism, that it not only supports the journals now in existence, but actually crowds their columns with communications. These periodicals, instead of soliciting contributions, have to apologize for want of space to insert such as are freely offered, and the inevitable consequence is, that much very valuable material is allowed to waste for want of utilization. We have been impressed with this fact for a long time past, and have on that account concluded that not only was there room for a weekly journal, but that the existence of such a periodical was

every year becoming more and more a necessity. We have always believed in weekly medical journalism, and have striven for the past nine years to prepare THE RECORD to occupy this field. To this end we have been content to work along quietly until the necessities of the occasion became apparent, and when the success of the journal was sufficiently well established to render the desired change pecuniarily safe. That time has now arrived, and we embark upon our new and long-cherished enterprise not without a reasonable hope that our efforts to make this journal a representative of its class will be successful.

New York may justly be considered a medical centre. Its hospitals, societies, colleges, and periodicals are all in a prosperous condition, and every year it is increasing its facilities for medical instruction and developing its resources for medical progress. The wealth of the city tempts the large majority of the best men of the country to cast their lot among us, and the lively competition to excel in the different departments of practice is visible in all their associations with each other. We venture to say that never before were we, medically speaking, in a more prosperous way, and that never before was there offered a better opportunity for laying the foundation of a prosperous weekly. While all the other periodicals can continue to work as heretofore in their respective spheres, there is such an abundance of material that could not be utilized by any other means, that we cannot conceive that we are trenching upon the rights of any of our brethren by making the change which we propose.

In entering this field of weekly medical journalism, in this city and at this time, we cannot fail to appreciate our responsibilities, and in the performance of the labors connected with our undertaking we are not unmindful of the necessity of appealing to such of our old friends as have helped us heretofore. To them, immeasurably more than to us, has the success of THE RECORD been due. The first authorities in our land have liberally contributed their best productions to its columns, and many times we have been cheered by communications written especially for us by gentlemen in foreign countries. We have been honored by quotations in nearly every medical journal of the world, and have been the means of conveying the news of medical progress in this country to every section of the globe. At no time have we been denied the heartiest sympathy of the medical leaders of this city. We have endeavored to profit by their influence and counsel, and have studied to make the journal thoroughly representative of the profession of New York.

In its general editorial management it has been our aim to be strictly impartial, and every consideration has been secondary to that of ministering to the more pressing wants of the daily practitioner. Not bound to any clique, nor under the control of any spe-

cial influence, we have tried to make THE RECORD a thoroughly independent journal. In the discussion of all subjects, great and small, we have been impelled to exercise that spirit of honesty which seeks for the truth, and to be fearless in our denunciations of what we believe to be error. Believing that such a course best meets the desire of the profession, and is the only way to vindicate the rights of impartial criticism, we intend to continue it.

In regard to the contents of the journal, we do not desire to make any extravagant promises. Suffice it to say, that, with the help of an increased staff, we shall endeavor to take every opportunity to improve the facilities which New York affords for making it a first-class weekly.

THE PHYSICIAN AS A WITNESS.

WITH many medical men there is an ambition to make a reputation as experts in courts of law. The reason for this is doubtless in a great measure owing to the difficulties in the way of such a distinction. There is, perhaps, a laudable pride on the part of such gentlemen in being considered too smart for the cross-questioning counsel. Very few, however, appreciate the fact that a conceited and indiscreet witness is a legitimate prey to cross-examination, and that the avowed design on the part of the so-called persecuting lawyer is to prove to the jury that the doctor is an ignoramus and that his opinion is of no value. This can very readily be done by skilful manœuvring on the part of the attorney, and if the doctor is not extremely guarded in his replies he is always worsted. The advantage on the part of his interrogator must be acknowledged when we admit that it is always easier to ask questions than to answer them. Lawyers know this as well as physicians, but the jury is not always able to draw the proper line of discrimination. Legal gentlemen always have a high respect for the learned professions; but every consideration of this sort sinks in entire insignificance when the interests of their client are at stake. Professionally speaking, we have no right to expect any mercy from them, and we cannot, consequently, be too ready to protect ourselves. We must be ready to admit from the start that the fight is not a fair one, and prepare ourselves accordingly.

The Hon. John T. Hoffman, in an address recently delivered to the graduating class of the Albany Medical College, gives the following advice, which commends itself to every one at all interested not only in making an impression as an expert witness, but in saving his reputation as an ordinarily educated medical man:

"When you go upon the stand as a witness, go well informed, but not too full of learning in the matters about which you are to testify. Confine yourself to facts, and do not be forced into theories any further than you can help. Use the simplest language you can adopt, and omit as far as practicable purely profes-

sional terms and phrases. Speak English and not Latin, for the jurors are not ancient Romans. Remember that the witness-box is the place in which to tell the plain truth, not to display learning. Meet quick questions with slow answers. Answer long questions with few words. Above all, keep cool. . . ." These rules are very simple, are founded on the plainest common-sense, and yet how often are they violated!

MARINE HOSPITAL SERVICE.

IN another column we publish a bill recently introduced in the Senate by Senator Cameron, to which we wish to call the attention of our readers. The intention of the said bill is to place the medical part of the Marine Hospital Service on a fair basis, and take it out of the lower regions of politics as much as possible. Ever since the Marine Hospital Service has had an existence there has been a great necessity for legislation upon the matter, and in the present effort there is a promise that a great deal of good will be accomplished.

THE ARMY STAFF RANK BILL.

THE Committee of the American Medical Association are again before Congress with a bill for increasing the efficiency of the Army Medical Staff. Notwithstanding the defeat of last year, there is a determination on the part of the profession to test the merits of the case in another struggle; and every individual physician should feel enough interest in it to exert all his influence in the proper direction. We shall take occasion hereafter to discuss the merits of the bill in detail.

A BUILDING FOR THE ACADEMY OF MEDICINE.

AT a recent meeting of the Academy of Medicine, to which the profession generally was invited, it was determined to secure a building for the accommodation of the different medical societies of the city. This, so far as it goes, is a good commencement, and if the proposed plan succeeds, it may be the foundation of an institution of which the medical fraternity of this city may be proud. After the habitation has been obtained, the difficulty will be in giving it a suitable name.

A DEPARTMENT FOR CHILDREN IN BELLEVUE.

THE Medical Board of Bellevue Hospital has established a special department for the treatment of diseases of children. It is to be under the charge of Dr. A. Jacobi, one of the attending physicians recently appointed. There are no classes of disease more frequently met with by the practitioner, and none which require more careful, judicious, and skilful treatment than those belonging to early childhood. A want has long been felt for clinical instruction in this branch, and in such a large hospital as Bellevue the facilities offered are unequalled anywhere.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Nov. 25, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

(Concluded from page 653, vol. ix.)

ANTERIOR STAPHYLOMA OF THE EYEBALL.

DR. H. KNAPP exhibited an eyeball which had been removed by operation and sent him by one of his former pupils, DR. SWAN M. BURNETT, of Knoxville, Tenn. The patient, a boy 15 years of age, when 18 months old was struck in the eye by a piece of china-cup. A scar formed in the cornea and the pupil was closed. The eye was blind, but not misshapen until three or four years ago, from which time it steadily enlarged. It never was painful, nor caused inconvenience to the other eye, and was removed merely to remedy the deformity.

All the diameters of the globe are enlarged, the anterior-posterior more than the others. There is a scar running nearly vertically across the whole cornea. A meridional section shows iris and lens capsule connected with the scar. The lens is shrunken and displaced, being united to the corneal scar by a cord of capsule. The cornea is enlarged. The sclerotic, between the margin of the cornea and the corona-ciliaris, is thinned and greatly distended. The ciliary body and posterior structures of the globe are in their natural position and apparently unchanged, with the exception of the optic nerve, which is deeply cupped. The distention of the globe is caused by the corneo-ciliary staphyloma, which is so manifest that the ora serrata is as remote from the cornea as it is from the optic disk. The enlarged parts of the sclerotic and cornea are covered with a thin layer of atrophic iris, which arises from the ciliary processes.

The specimen is interesting, not so much on account of the changes of the globe, for these are known well enough, as on account of the history of the case. A penetrating wound in early infancy had produced a dense cicatrix through the whole extent of the cornea, in which the iris and lens had been implicated. The eye had become blind, but retained its shape for ten years. Then it began to enlarge steadily, but never was tender nor caused irritation in its fellow. The case exemplifies the theory that wounds and cicatrices in the cornea, iris, and lens are not prone to excite sympathetic ophthalmia, as long as the ciliary body is not involved in the morbid changes.

DR. DELAFIELD remarked that pain in such eyes, was, in his opinion, due more to injury to the vitreous than to the ciliary body.

DR. KNAPP remarked that this was an observation new to him, and he thought that every specimen tending to elucidate that point was valuable. In regard to the matter of sympathetic irritation from wound of the vitreous, he related the case of a boy from whose vitreous he extracted a fragment of a cap, within three hours after the injury. The operation had been performed ten years ago, in Heidelberg, and up to last summer, when he last saw the case, there had been no trouble whatever with the other eye.

DR. DELAFIELD stated that his remark in regard to wound of the vitreous referred to the element of pain simply, but not to sympathetic irritation

DR. THOMSON referred to a case of wound of the vitreous in a lady under his charge, who had been free from sympathetic irritation for seventeen years.

The Society then went into executive session.

NEW YORK MEDICAL JOURNAL AND LIBRARY ASSOCIATION.

Stated Meeting, Nov. 27, 1874.

DR. J. C. PETERS, PRESIDENT, in the Chair.

NITRITE OF AMYL AND BELLADONNA IN DYSMENORRHEEA.

THE paper for the evening was read by Dr. Mary Putnam Jacobi, upon "Nitrite of Amyl and Belladonna in Dysmenorrhœa."

The clinical history of three cases was given to illustrate the method of operation of the above remedies. All three were cases of severe spasmodic dysmenorrhœa. They were treated by administering belladonna for several days previous to the recurrence of menstruation, and nitrite of amyl by inhalation during the paroxysm. This treatment, it was believed, had a rational basis.

The argument in its support was founded upon the data furnished in the second case, in which were manifested three sets of phenomena:

- (1.) Vomiting, pallor of skin, cold hands and feet.
- (2.) Extraordinary peristaltic action of the intestines.
- (3.) Spasmodic pain in the uterus.

All these point towards one element, namely, that of spasmodic contraction of blood-vessels.

First, the so-called sympathy between the uterus and the stomach, and between the stomach and brain, were fully considered in their dependence and interdependence with reference to the symptom, *vomiting*.

It was believed, reasoning from the experiments of Schiff and others, that the vomiting of pregnancy, vomiting of sea-sickness, and many cases analogous in character, was due to the same cause, namely, anæmia of the brain, producing spasmodic contraction of blood-vessels at its base.

It was further argued that anæmia of the intestines produces contractions or increased peristalsis, due to spasmodic contraction of blood-vessels.

There are three conditions in which a hollow muscular organ can contract in the state of vacuity.

- (1.) After direct irritation of its nerves.
- (2.) After direct irritation of its muscular fibre.
- (3.) After changes in its circulation.

A detailed account of six experiments was given. The experiments had been performed upon rabbits. The abdominal cavity was opened, the intestines drawn out and carefully protected in a bag of oil-silk, which was kept immersed in a vessel of warm water; the uterus exposed, and the abdominal aorta exposed. The aorta was then compressed with a ligature, and the result carefully noted.

Several waves of peristalsis ran *down* the rectum, but never in a contrary direction. Contraction of the uterus occurred, and was distinctly visible at the middle third of the organ. Upon removal of the ligature the contractions ceased. The time at which contractions appeared after compression of the aorta was made, also the duration of the contraction after compression had been removed, were carefully noted. The conclusion made from the experiments was, that tonic contractions of the uterus may be excited by occlusion of the aorta, and that such contractions continue from one

to four minutes after compression has been removed. Clonic contractions also occurred, after the type of contractions of masses of smooth muscular fibre.

What bearing do the results of these experiments have upon the treatment of spasmodic dysmenorrhœa? The pain in these cases is dependent upon tonic and clonic contraction of the uterus.

These, in turn, are dependent upon some cause. Of the conditions in which a hollow muscular organ can contract in a state of vacuity, direct irritation of muscular fibre and direct irritation of nerves were excluded. Consequently we are obliged to fall back upon changes in the circulation of the uterine walls. If the change of the blood-vessels passes to an irritation, spasmodic contraction must take place, and uterine contractions will be determined by local anæmia.

Spasmodic contraction of blood-vessels resulting from irritation of vaso-motor nerves is the cause of the pain of spasmodic dysmenorrhœa. It is upon these considerations that the remedies suggested are used. The *secondary* effect of belladonna is dilatation of the blood-vessels.

Belladonna is to be administered, therefore, previous to the occurrence of menstruation, for the reason that it is desirable to obtain the *secondary* effects of the remedy.

Nitrite of amyl is used for the purpose of relaxing blood-vessels. This is in accordance with the admitted physiological action of the remedy.

This method of treatment, of course, is more especially adapted to cases of spasmodic dysmenorrhœa; but it has been found, both in the experience of the author of the paper, and in that of others, that great relief may be afforded even in those cases in which the dysmenorrhœa depended upon displacements, constriction of the cervix, etc.

The method is, to administer belladonna in ordinary doses for several days previous to the occurrence of the menstrual flow, and when pain comes, to administer by inhalation from two to six drops of the nitrite of amyl *p. r. n.* In one case a single drop of amyl was all that was required.

DR. SELL remarked that he had been in the habit of administering nitrite of amyl by the mouth, and had obtained just as good results as he had obtained when the remedy had been inhaled. He prescribed it in one-drop doses, combined with drachm doses of peppermint water, and repeated every half hour. In one case of dysmenorrhœa, and one only, he had used the nitrite of amyl, and in that case the patient was completely relieved of pain.

Drs. Pallen and Peaslee did not feel prepared to discuss the paper.

Annual Meeting, Dec. 4, 1874.

In absence of DR. J. C. PETERS, President, the Association was called to order by Vice-President DR. FARNHAM.

The address of Dr. Peters, the retiring President (who had been unexpectedly called from the city), was read by the Corresponding Secretary of the Association.

The address was highly complimentary to the President elect, and also contained congratulatory reference to the continued success and prosperity of the Association.

After the reading,

DR. EDMUND R. PEASLEE, President-elect, took the

chair, and briefly responded to the address of the retiring President.

CYSTITIS, ITS SIGNS AND TREATMENT.

The subject for the evening was then presented by DR. A. B. CROSBY, upon "Cystitis, its Signs and Treatment."

Dr. Crosby remarked that he proposed to occupy one hour in the consideration of the subject of *chronic cystitis*, and more especially with reference to some points in its treatment.

Nothing new was expected to be added to our knowledge, on account of the thorough investigation and presentation of the subject made by previous writers.

Chronic cystitis was to be regarded rather as an effect than a disease *per se*. In the young and middle aged it was usually curable. In the old, however, and when certain organic changes have occurred in connection with the bladder itself, it was an exceedingly intractable disease; but often here the surgeon may do much to palliate the sufferings of the patient.

Causes.—Acute cystitis may become chronic. Anything which obstructs the free flow of urine from the bladder (decomposition of urine remaining in bladder takes place and excites inflammation).

Paralysis.—This results in retention; retention was very liable to be attended by over-distention of the bladder; this over-distention produces by pressure an anæmic condition of the capillaries of the walls of the bladder; sudden removal of the pressure, by means of the catheter, permitted the sudden return of blood, and inevitably hyperæmia, and frequently inflammation follows.

Excessive alkalinity of the urine, either artificial or accidental, or excessive acidity of the urine may give rise to chronic inflammation of the bladder.

Renal diseases, especially those which tend to suppuration.

Excessive diuresis was claimed by some to be a cause.

Presence of foreign bodies in the bladder, such as calculi and foreign growths.

Diseases of contiguous organs (bad cases of hemorrhoids and sometimes diseases of the uterus).

These are the essential causes.

Two distinct varieties were generally recognized.

(1.) Little more than an irritable condition of the bladder; (2.) A cystitis more severe and more persistent in its character.

In the first there was certainly hyperæmia and hyperæsthesia, if not real inflammatory action. There is frequent desire for micturition, increase in the amount of mucus, and almost inevitably present a certain amount of pus, although it requires the microscope to demonstrate it.

Any irritation can induce this condition. The removal of the cause almost always resulted in a speedy convalescence. This could be hastened by absolute rest, free use of warm-water injections, hip-baths, fomentation over perineum and hypogastrium, maintaining a soluble condition of the bowels, and administering alkalies, anodynes, and demulcents.

In the second variety of chronic cystitis there was a passive or congestive hyperæmia of the mucous lining of the bladder, attended with great irritability and over-distention of the walls of the capillaries. There was usually a certain amount of hyperæsthesia, but comparatively moderate in its character. There was an inordinate quantity of mucus and pus in the urine coming from a bladder thus inflamed. It was the condition known as the chronic catarrhal inflammation of

the bladder. The urine contains a marked sediment, of semi-transparent, ropy, and tenacious material.

Some surgeons have considered the deposit to be purely mucus; others have regarded it as simply an exaggeration of the prostatic secretion; others still farther, that it was simply pus mingled with alkalis. It was doubtful whether either opinion was correct. There was pus, but it did not present the same appearance as did pus with an alkali outside of the body.

It had been claimed by some that the mucous membrane of the bladder has a perversion of the secretory power under these circumstances. The lining membrane was practically in that condition seen in catarrhal inflammation of the bronchial tubes, and that which was known as bronchorrhœa had marked points of resemblance to cystorrhœa, the term employed in connection with those cases of cystitis which are characterized by such an inordinate quantity of semi-transparent material.

With reference to treatment, a very great variety of plans had been devised. Almost every writer upon this subject ventured upon antiphlogistic treatment; but this should be rejected. The disease was essentially one of debility and relaxation, and the indications were to give to the patient certain tonic and astringent effects.

The treatment divided itself into local and constitutional.

With reference to *local* treatment: (1) free the lining membrane of the bladder from everything in the way of inorganic matter which may accumulate there; (2) cleanse the mucous membrane as thoroughly as possible.

Free the mucous membrane by introduction of catheter once or twice every twenty hours, if the patient was unable to empty his bladder completely, and then wash the bladder out with some form of injection. For this purpose an almost endless variety of injections had been recommended, and only some of the most serviceable would be mentioned.

Injections should be used at about the normal temperature of the body.

R. Acetate of lead..... gr. $\frac{1}{6}$.
Water..... ʒi.

M.

R. Nitrate of silver..... gr. i.
Water..... $\frac{5}{8}$ ʒij.

M.

gradually increasing the silver until a strength of one grain to one drachm of water may be used.

There were those who believed that there was an excess of earthy phosphates, and that the sediment in the urine was liable to accumulate in the bladder; consequently they recommend the use of water acidulated with nitric acid as an injection, for the purpose of dissolving the phosphates.

R. Nitric acid..... gtt. ij. to iv.
Lukewarm water..... $\frac{5}{8}$ ʒ.

M.

Simple warm water might be injected. The quantity of fluid injected should never exceed $\frac{5}{8}$ ʒij. some say. He did not believe that such a rule was to be generally adopted. If the injection was practised slowly, so as not to irritate the bladder by sudden rushes of the fluid, a much larger quantity can be borne without producing irritation. Any indication, however, that the distention gave increased pain, should of course warn the surgeon to diminish the quantity injected. Having made the injections, they should be allowed to remain from two to three minutes before being permitted to flow away.

Sometimes the urine is distinctly fetid. In such

cases carbolic acid would be serviceable; used one drop of the saturated solution to a pint of water.

In those cases in which there is considerable pain present, anodyne substances might be injected.

Whatever anodynes were injected into the bladder, a small portion should be allowed to remain, in order for absorption to take place.

Whatever injection is used, it is well to observe precaution, and manipulate the bladder in the mildest manner possible. During the last three or four years he had used permanganate of potash by injection in those cases.

This substance was exceedingly rich in oxygen, and when it came in contact with pus, or organic matter, it tended to decomposition very rapidly. The oxygen being set free when in this nascent state, seized upon the organic germs and burned them up.

The salt was used of the strength of one-half grain to the ounce of water, and diminished in strength if pain, heat, or irritation is produced either at the time or just after the injection has been used. The injection, when it returned, was quite likely to be of a dusky appearance.

After injecting the bladder with the solution of the potash once or twice a day, according to circumstances, and continued for a few days, he had been accustomed to inject the bladder with water, acidulated with hydrochloric acid, in the strength of four to six drops to eight or ten ounces of water. The hydrochloric acid would dissolve the deposit of the potash, if any there be, and the patients are generally more markedly improved by alternating these injections.

Counter-irritation.—Fly-blisters have been said to be contra-indicated, but his experience had led him to believe that they would not give rise to any increase of the trouble. Hot poultice with mustard offers a very fine and moderate counter-irritation. Anodynes were especially indicated to relieve pain, diminish nervous irritation, and procure sleep. Warm hip-baths at bedtime were admirable. The bowels required careful attention, and should be kept in a soluble condition. For this purpose, inspissated ox-gall was very useful. The sacculi of the rectum should be kept perfectly free from fecal matter. Upon the whole, the administration of *internal* remedies was unsatisfactory. When frequent desire to micturate was present, decoction of *uva ursi* was the best. When inflammatory action was slight, *buchu*, *cubebæ*, *copaiba*, *turpentine*, have all answered a good purpose. If vegetable substances were employed we should use them *freely*, and they should be administered at short intervals if we would get the greatest benefit from them. Decoction of *pareira brava* was a favorite with many. When the cystitis was dependent upon obstruction, such as stricture of the urethra, *triticum repens*, $\frac{5}{8}$ i. to the pint of water, and taken within twenty-four hours, would be of much service. Demulcents were always in order. Shall the remedies be alkaline or acid? This is a question which sometimes troubles the young practitioner. Clinically it depends to a great extent upon the period of the disease which we have to treat.

During the earlier part of the disease he had been accustomed to use alkalis, such as liquor potassa, etc., combined with camphor mixture and sufficient opium to control pain. Later in the disease, when the discharge is large in quantity, acids had but little influence in changing the reaction of the urine. Nitromuriatic acid, with quinine, might be of benefit by changing the tone of the system.

It was claimed that benzoic acid had the power, in these advanced stages, to render the urine acid.

Diet should be light and thoroughly nutritious.

Malt liquors are contra-indicated. In elderly persons alcohol did not particularly irritate the bladder; and certainly *gin*, associated with nux vomica, was very excellent in many cases. The surgeon should render himself certain that there was present no obstruction to the portal circulation. Absolute rest, and confining the patient to a perfectly equable temperature, were very essential.

Diathesis.—If there is markedly gouty or rheumatic diathesis, or malarial taint was present, you cannot hope for permanent benefit, unless you first combat the diathesis from which the patient is suffering.

DR. BRADLEY mentioned some cases in which the cystitis was dependent upon stricture of the urethra. He had divided the strictures agreeably to the suggestion of Dr. Otis, and the operation was followed by great relief. The injections used were nitric acid gr. ij. to the ℥i. of water, combined with large quantities of hyoscyamus.

DR. ROBERT NEWMAN advocated systematic dilatation of the bladder, for the purpose of overcoming the contraction that had occurred in the viscus as the result of the disease. He had had some patients who could not endure more than a tablespoonful at first, but dilation was carried on until the patient could retain one pint without inconvenience.

He also mentioned the fact that exceedingly strong solutions of nitrate of silver could be applied to ulcerated surfaces within the bladder by means of the endoscope, without producing undue irritation, when a very weak solution would produce great irritation introduced as an injection. Among the causes he mentioned the habit in our public schools of not permitting girls, especially, to go out when they desire to evacuate the bladder.

DR. SELL mentioned the fact that Dr. Heath, of London, was in the habit, in the treatment of cystitis in the female, of using nitrate of silver of the strength of one scruple to the ounce of water. It was applied by first dilating the urethra with the finger, and introducing the solution through a hard-rubber syringe.

In some cases simple dilatation of the urethra was sufficient to effect a cure.

DR. PEASLEE remarked that the item of rest, absolute rest, was very important in the treatment of chronic cystitis. In some cases in the female it becomes necessary to produce an artificial vesico-vaginal fistula. Sometimes it became necessary to keep such fistula open for a year. Then, if the bladder is much distended, the cystitis will be brought back again. This seemed to argue that dilatation was not, as a rule, admissible. With regard to the injection of morphine, it had been questioned whether the bladder had any power to absorb at all. But it seemed to him that the bladder had decided power of absorption, even where there was no reason for suspecting ulceration. He did not believe that cystorrhœa, bronchorrhœa, leucorrhœa, and those conditions characterized by an excessive discharge of secretion normally present were due to inflammation. They are due rather to passive congestion, and true inflammation is not reached.

DR. GARRISH closed the discussion.

DR. A. B. CROSBY, Professor of Anatomy at Bellevue Hosp. Med. College, is delivering a series of lectures on Physiology, as a part of the Cooper Union Free Lectures; and is to be followed by PROF. GEO. L. GOODALE, of Harvard College, who is to lecture on Botany. All the lectures of the latter course are to be illustrated by the use of the stereopticon.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, December 3, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

MINUTES of previous meeting read and approved.

NOMINATION OF OFFICERS.

For President—Drs. Purple, Buck, J. R. Wood, Stone, and Barker.

For Vice-President—Drs. Gouverneur M. Smith, and R. A. Barry.

For Trustee—Drs. A. Flint, Anderson, Stone, Burroughs, and A. C. Post.

For Committee on Admission (one vacancy)—Drs. Blumenthal, Carroll, and C. B. Tucker.

For Committee on Medical Ethics (one vacancy)—Drs. Cheesman, Joel Foster, Stone, and Adams.

For Committee on Medical Education (one vacancy)—Drs. Gurdon Buck and Peaslee.

The Corresponding Secretary announced the reception of certain volumes.

Treasurer's report read and accepted, showing a balance in the treasury, November 16, 1874, of \$558.13.

Trustees' report read and accepted, showing the assets of the Academy to be \$15,009.

Report from Committee on Admission read and accepted, showing that eleven resident fellows, one honorary fellow, and five corresponding fellows had been elected during the past year.

The remaining annual reports and reports from sections were read and received.

REPORT OF COMMITTEE OF WAYS AND MEANS

was next presented by Dr. Anderson, showing that the amount of money now in the hands of the committee available for building purposes is \$28,492. Report accepted.

The Academy took a recess of one hour for the purpose of discussing the question of securing a house for the Academy and the medical profession of the city.

Dr. Oliver White was called to the chair, and Dr. Ellsworth Eliot was made secretary.

Discussion was opened by Dr. Willard Parker, and continued by Drs. Barker, Peaslee, Anderson, Hubbard, Flint, Sayre, and Caro.

DR. FLINT offered the following resolution:—

Resolved, That it is the sense of the medical profession, as represented in this meeting, that the Committee of Ways and Means of the Academy of Medicine should, *without delay*, take steps to obtain a building suitable for the accommodation of the Academy and other medical societies of this city; and that it is also the sense of this meeting that the committee should feel themselves warranted, if necessary, in incurring a debt of ten or fifteen thousand dollars for that purpose.

The resolution was adopted.

The Committee of the Whole then arose and reported to the Academy the action taken.

The report was referred to the Committee on Ways and Means, as expressing the views of the profession represented in the meeting held, and with the request that the committee should report to the Academy as early as practicable. Adjourned.

"HOSPITAL SUNDAY IN NEW YORK."—Bishop Potter has recommended that the collections taken in the Episcopal churches of this city, on the 27th of Dec., be devoted to the support of St. Luke's Hospital, which is in need of funds.

NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

Stated Meeting, November 16, 1874.

THE PRESIDENT, DR. MEREDITH CLYMER, in the Chair.

DR. J. W. S. GOULEY presented some specimens of *curare*, and made some remarks on its sources of supply, history, and supposed composition, and its therapeutic uses. The South American Indians make at least two kinds, one for their own use, and one of inferior quality, for sale. The specimens exhibited were of the most esteemed variety, from the Rio Negro. The several diseases in which it has been tried were named.

DR. E. R. SQUIBB remarked that the *curare* hitherto used was obtained from various sources, and in some specimens strychnia and brucia had been detected. Being of such variable composition the physiological action must greatly vary, and hence, he thought, *curare* could not be brought into general therapeutic use. Of any given specimen, the dose can only be ascertained by first showing the physiological effects. Even if the alkaloid were discovered, it could not be produced in sufficient quantity for general use.

DR. J. W. S. ARNOLD had noticed that in the same good there was a weaker yellowish-gray external layer, and an anterior dark glutinous mass of much greater strength. He had noticed, too, that the poisonous dose was variable for different animals of the same species.

DR. W. A. HAMMOND had obtained, some fourteen years ago, a specimen of *curare* of the kind known as *corroval*, the action of which differed markedly from that of other varieties. Ordinary *curare* spares the heart whilst paralyzing the voluntary muscles. The primary effect of *corroval* is to stop the heart. He had had no experience with ordinary *curare*; but in a case of traumatic tetanus in a colored boy he had tried hypodermically *corroval*; the effect was to lessen the spasms, and markedly retard the pulse; after the third dose this retardation went on to failure. He believed *curare* to be of purely vegetable composition, as with the microscope he had failed to find animal debris.

DR. J. C. DALTON said he could corroborate what had been said concerning the different effects of the different specimens of *curare*. There is probably no regular formula for its preparation, each tribe having its own secret. It is evidently an extract, containing a large amount of vegetable matter. The failure to detect animal debris with the microscope might be accounted for by their destruction in the manufacturing process. Its action resembled that of an animal poison. He had noticed the difference between ordinary *curare* and *corroval* in the influence of the latter on the heart. [Dr. D. exhibited several specimens of *curare*, some of which, though fifteen years old, had been lately used with prompt effect.] He thought that the great uncertainty of the substance was a bar against its therapeutic use.

Further remarks were made by Dr. A. Flint, jr., E. R. Squibb, J. C. Dalton, W. A. Hammond, and Beard.

DR. L. DUNCAN BULKLEY read a paper on "The Relations of the Nervous System to Diseases of the Skin."

After briefly reviewing the *microscopic anatomy* of the skin, the author passed to the close physiological relations between the skin and the other organs, evidently the result of neural connection, as shown in the various conditions cited, and then mentioned the

pathological observations which were found to be conclusive as regards the close relations between nerve influence and the nutritive changes in the skin, on which he rested his argument for the neuro-pathology of so many skin diseases. Whilst nerve-section, or nerve-abnegation is incapable of exciting these disorders, nerve-irritation is abundantly able to do so; and it is nerve-irritation which is excited by the deposits of leprosy and syphilis, or by the circulation of the effete products of gout, rheumatism, serofula, etc., or the ill-assimilated elements in dyspepsia, constipation, oxaluria, and the like. A large number of skin diseases may be the result of reflex nervous action. The nerve elements in eczema, urticaria, pruritus, prurigo, erythema, etc., are plain enough to make us desire a fuller knowledge of their relations.

Remarks were made upon Dr. Bulkley's paper by Drs. W. H. Draper, E. L. Keyes, etc. The Society, after going into executive session for the nomination of officers for the ensuing year, adjourned.

Correspondence.

INCISED WOUND OF TENDO-ACHILLIS.

ST. PETER'S HOSPITAL, 54 BERNERS STREET,
LONDON, W., December 14, 1874.

TO THE EDITOR OF THE MEDICAL RECORD, NEW YORK.

MY DEAR SIR:—Whilst in London, for hospital observation, being honored in the serving as house-surgeon to the Stone Hospital, I casually overlooked the files of THE MEDICAL RECORD in the library of the Royal College of Surgeons, whilst there yesterday, and accidentally fell upon an article from T. H. Kearney, M.D., Professor Principles of Surgery Miami Medical College, Cincinnati, O., in the July 15th, 1874, number, referring at length to a case of incised wound of the tendo-Achillis, reported by me before the Medical Board E. D. New York, and published as part of their "Proceedings" in the May 15th, 1874, number of THE RECORD.

For the sake of the almost twin-like resemblance of the cases there referred to, except alone the history of the professional services rendered to our patients—in Dr. Kearney's case I believe about three (3) months, in my case not three (3) weeks—the facts, as far as there given cannot, I regret to say, be modified by anything known later as to my particular case, as it was an instance of "Poor preach, poor pay," my patient as studiously eluding my professional eye as the stony gaze of my disappointed collector.

GEO. H. MITCHELL, M.D.

PUERPERAL FEVER IN THE NEW MATERNITY AT BONN.—In a letter to *The Lancet*, Nov. 28, 1874, a correspondent writes, concerning the new Gynæcological Institute at Bonn:

"It is a singular fact that puerperal fever broke out immediately after the opening of the hospital, and six patients died from it, while since that time there has not been a single case of the disease."

EXTIRPATION OF THE LARYNX.—Professor Billroth performed this operation for the second time on November 11th, in the General Hospital of Vienna, on a man, aged fifty, suffering from epithelioma of the larynx. The patient died at midnight, on the 16th, apparently from hypostatic pneumonia.

Medical Items and News.

MARINE HOSPITAL SERVICE.—The following Bill, to promote economy and efficiency in the Marine Hospital Service, has been introduced into the Senate by Senator Cameron:—

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That the Secretary of the Treasury shall cause to be prepared a schedule of the average number of seamen required in the safe and ordinary navigation of registered, enrolled, and licensed vessels of the United States, basing such schedule upon the differences in rig, tonnage, and kind of traffic. And hospital dues at the rate and for the periods prescribed in sections 4585 and 4587 of *The Revised Statutes of the United States* shall be assessed and collected, from the master or owner of each vessel subject to such dues, upon the average number of seamen as set forth in said schedule: *Provided,* That nothing herein contained shall be held to debar masters or owners of vessels from deducting such dues from each seaman's wages, as by law now authorized.

Sec. 2. That the term "seaman," wherever employed in legislation relating to the Marine Hospital Service, shall be held to include any person employed on board, in the care, preservation or navigation of any vessel; or in the service, on board, of those engaged in such care, preservation, or navigation.

Sec. 3. That the Secretary of the Treasury may rent or lease such marine hospital buildings and the lands appertaining thereto, as he may deem advisable in the interests of the marine hospital service; and the proceeds of such rents or leases are hereby appropriated for the said service.

Sec. 4. That insane patients of said service shall be admitted into the Government Hospital for the Insane upon the order of the Secretary of the Treasury; and shall be cared for therein until cured or until removed by the same authority; and the charge for each such patient shall not exceed four dollars and fifty cents per week, which charge shall be paid out of the marine hospital fund.

Sec. 5. That sick and disabled seamen of foreign vessels, and of vessels not subject to hospital dues, may be cared for by the marine hospital service at such rates and under such regulations as the Secretary of the Treasury may prescribe.

Sec. 6. That the corps of medical officers of the marine hospital service shall consist of one supervising surgeon, surgeons, and assistant surgeons, all of whom shall be appointed by the President, by and with the advice and consent of the Senate, and upon the recommendation of the Secretary of the Treasury after such examination into professional qualifications as he may from time to time direct.

Sec. 7. That the compensation of said officers shall be paid out of the marine hospital fund, at the following rates: the supervising surgeon, dollars per year; surgeons not more than dollars per year, nor less than dollars per year each; assistant surgeons not more than dollars per year each. And the Secretary of the Treasury may prescribe the rate of pay for surgeons and assistant surgeons within these limits, and in accordance with the nature and extent of the duties assigned.

Sec. 8. That all acts and parts of acts inconsistent with this act are hereby repealed.

DR. JOHN P. GRAY, Medical Superintendent of the State Lunatic Asylum at Utica, New York, will commence on Tuesday, the 5th inst., at 1.30 p.m., a series of lectures at the Bellevue Hospital Medical College on Diseases of the Brain, the Mind, and the Nervous System, to which the profession are invited. The dates and subjects of the lectures are as follows:—Jan. 5th, General Considerations, and Terms used; Jan. 12th and 19th, Etiology, Forms of Insanity and Diagnosis; Jan. 26th, Pathology, with Illustrations; Feb. 2d, Treatment and Prognosis.

NEW MEMBERS OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the stated meeting held Dec. 28, the following gentlemen were admitted to membership: STEPHEN DE WOLFE, 138 W. 37th St., a graduate in medicine at the Univ. of Pennsylvania in 1845; WILLIAM H. FARRINGTON, 7 W. 45th St., a graduate in medicine at the Bellevue Hosp. Med. Col. in 1872; EZRA S. McCLELLAN, a licentiate of the State Medical Society in 1874; FRANK D. BEANE, 217 W. 10th St., a graduate in medicine at Columbia Medical College in 1871, and at Bellevue Hosp. Med. College in 1874; and JOSEPH D. BRYANT, 28 W. 36th St., a graduate in medicine at Bellevue Hosp. Med. College in 1868.

THE VACCINATING CORPS of the Board of Health have, within the past two months, visited all the tenement-houses on the avenues in this city between Eighty-sixth St. on the north, and Bleecker and Canal Sts. on the south, and measures, it is said, are being taken to examine, as far as possible, after a suitable time, all infants certified to have been born in the city, and insure their proper vaccination.

MEDICAL GRADUATES.—The Medical Colleges of the United States graduated in the year 1874 three thousand students.

MEDICAL RECEPTIONS IN NEW YORK.—Some of the medical gentlemen of this city have issued invitations for weekly evening receptions at their houses during the winter.

DR. MARY PUTNAM JACOBI, during the recent meeting of the New York Pathological Society, temporarily occupied the chair during the presentation of a specimen by the president. This is one way of answering the question of women's rights in medicine.

THE *London Lancet* nets an annual income of nearly twenty-five thousand dollars. So much for being independent.

THE JOURNAL OF PSYCHOLOGICAL MEDICINE, which was edited by the late Forbes Winslow, is to be published semi-annually, under the editorship of Dr. Lytleton S. Forbes Winslow, son of the former.

THE MEDICAL FACULTY OF THE UNIVERSITY OF BISHOP'S COLLEGE, of Montreal—now in its fourth year—has been placed on the list of medical schools recognized by the Royal College of Surgeons of England.

THE MANAGERS OF THE NEW YORK INFANT ASYLUM, (24 Clinton Place, and corner Tenth avenue and Sixty-first street), are to have their annual ball at the Academy of Music on the 14th inst.

DR. SAMUEL T. HUBBARD.—At the last meeting of the College of Physicians and Surgeons, Dr. Samuel T. Hubbard was elected a trustee, in place of Dr. Abram DuBois, resigned.

PROFESSOR AUSTIN FLINT, JR., has been appointed Surgeon-General of the State of New York, on the Staff of Governor Tilden, newly elected.

Original Communications.

EFFECTS OF THE
CONTINUOUS ACTION OF A HIGH TEM-
PERATURE ON THE NATIVES OF
TEMPERATE CLIMATES,
AS JUDGED BY THAT OF THE
LOWER RIO GRANDE REGION.

By P. F. HARVEY, M.D.,

ASSISTANT SURGEON U.S.A.

THE subject of climate, in its bearing upon the vital processes of the human race, is one of great interest to the profession, and our country, embracing an absolute range of temperature and a diversity of climate not much exceeded by any in the world, affords opportunities proportionate thereto for its study. Perhaps no class of men have better opportunities for the prosecution of this study than our army surgeons, whose field of duty and observation is commensurate with our territory.

It is doubtful if individual man is capable of adapting himself to every contingency of climate; it is certain that a protracted residence in hot and malarious regions exercises a persistent deleterious influence on most, if not all, northern constitutions. The races of Northern Europe find Louisiana an extreme climate, and they and their descendants are no longer to be recognized after prolonged residence there. Acclimation to malaria is a myth; its pernicious effects upon the human frame are perceptible at once, and the longer the system is exposed to such action the more thorough its subjection. A European transplanted to the South, "complains bitterly of the heat, and becomes tanned; his plump, plethoric frame becomes attenuated; his blood loses fibrine and red globules; his mind and body become sluggish; gray hairs and other marks show that age has come on prematurely—the man of forty looks fifty years of age; the average duration of life is shortened, as shown by insurance tables, and the race in time would be exterminated if cut off from fresh supplies of emigrants from the home country." "The European in the Antilles *struggles with existence.*" Morell tells us that the European inhabitants of Jamaica, of Cuba, of Hispaniola, etc., have made no progress since their establishment there. The mortality among the troops and officers of the English army is greatest among those who have remained longest in India. Such is the graphic and no doubt faithful picture of the effects produced by the combined and continuous action of malaria and a high temperature on the natives of temperate climates, drawn by some of the best medical writers of the age.

The injurious effects of a high temperature *alone* upon the natives of colder climates, while not so speedy, are eventually manifest in most cases. "When an Englishman is placed in the most beautiful part of Bengal or Jamaica, *where malaria does not exist*, he may live, with tolerable degree of comfort, his threescore years and ten, but he ceases to be the healthy individual he once was, and his descendants degenerate."—(Aitken.)

Many parts of Africa and India undoubtedly furnish climates more deadly to man than any to be found in this country; but the injurious effects upon the health of the northern native exerted by the climate of some

sections of our Southern States is much greater than is usually believed. I speak from an experience of six years passed mainly under the poisonous influence of malaria in the swamps of Louisiana and the exhausting heats of the lower Rio Grande. The deleterious action of malaria on the health is well understood and universally acknowledged by competent observers in this country; but the masses, while they recognize its hurtful nature, are scarcely aware of the destructive ravages it is capable of working in a comparatively short time, and that notwithstanding the adoption of precautionary measures. It is not, however, my intention to enlarge upon this point. The subject is well and fully represented in the writings of others. As premised, what I desire to show is the slower but not less sure deterioration wrought upon the constitutions of northern born people by the *pure unadulterated heat* of a hot climate, *free* from malaria, basing my remarks largely upon the results of personal experience and observation in the basin of the lower Rio Grande. During my stay in that section there must have been a remarkably small evolution of malaria, as I perceived none of its characteristic effects upon the troops; neither were the conditions favorable to its production. The soil is sandy and alkaline, and supports a scant vegetation, stunted mezquite (*algarobia glandulosa*) and cactus (*opuntia*) constituting the main growth. The rain-fall was confined chiefly to the autumn months, the meteorological register at Ringgold Barracks showing the annual fall to have amounted to about ten inches. The habit among the Mexicans of curing their beef in the open air showed that there was but a trifling amount of atmospheric moisture, and that desiccation rather than putrefaction of animal and vegetable substances took place. The agent above all others which tended to the production of disease was the excessive heat, and it performed its work in an insidious manner, but ultimately sufficiently evident to any not wilfully blind. The register at Ringgold Barracks showed the mean annual temperature at that point to be about 76° Fahr., only one degree cooler than that of Vera Cruz, and only 3° cooler than that of some places in the vicinity of the equator. The mean temperature of the spring months at Ringgold Barracks was about the same as that of the same season at Havana, but the summers were 5° hotter than those of the latter place. At Singapore, Malacca, under the equator (nearly) the mercury never rises higher than 85°. At Ringgold Barracks it was not a rarity to see it 25° higher than that, or 110° in the shade. That post is situated between the isothermal lines of 70° and 80°, corresponding to the central portion of Egypt.

The actual temperature to which persons are exposed is not accurately represented by a thermometer placed in the shade and screened from solar reflections. Many terrestrial and atmospheric conditions combine to affect the bodily temperature without materially affecting that represented by the thermometer. Some such were in operation at Ringgold Barracks. As is well known, heat is absorbed in different amounts by different soils. Sand containing lime possesses the greatest absorbing power. Herschel observed the temperature of the sand at the Cape of Good Hope to be no less than 159° Fahr. At Ringgold Barracks a thermometer recording over 140° Fahr. was exposed to the sun in the angle of a light-colored building where the reflection was considerable, and left for a few minutes. The mercurial column ran rapidly to the end of the tube, and meeting with resistance burst the bulb. The soil in the vicinity of Ringgold Barracks is composed chiefly of sand containing lime in con-

siderable quantity. In color it is light, and the reflection of the hot as well as the light rays of the sun is greatest from such soils. Hot winds, comparable to the simooms of Arabia, occasionally blew during the summer, generated by the extreme heat of the parched plains of Mexico. That Ringgold Barracks is situated in one of the hottest parts of our country is sufficiently evident from the meteorological register kept at that post, a short synopsis of which for the years 1871 and 1873 I give below:

1871.	Mean temp. in the shade.	Maximum in the shade.	Minimum in the shade.
Spring . . .	78.45°	109°	42°
Summer . . .	88.88	105	72
Autumn . . .	74.57	99	42
Winter . . .	60.86	92	32
1873.			
Spring . . .	75.06	106	30
Summer . . .	86.64	105	65
Autumn . . .	73.66	99	32
Winter	61.69	94	20 unusually low.

The mean maximum temperature for July, 1871, in round numbers was 102°. Can such an elevated temperature act otherwise than injuriously upon the races of the north?

It is not considered essential to the object in view to cite special cases. This could be easily done if deemed necessary; but a statement in general terms covering the field of my observation will, it is believed, meet the necessary requirements.

The question of diet is one of great importance in its bearing upon the health of persons from the North living on the lower Texan frontier. The system manifests a natural craving for a dietary in accordance with the temperature in which an individual is placed, provided the appetite is unperverted. In countries where nature furnishes a superabundance of heat the calorific articles of aliment are undoubtedly hurtful, and cooling fruits and vegetables the natural food of man. At Ringgold Barracks, inferior melons during the summer and oranges during the winter were practically the only fruits obtainable. Fresh vegetables were extremely scarce, while meat was furnished at low rates and in superabundance. Hence the diet may be looked upon as cooperating somewhat with the climatic influences, but to what extent I am unable to say. The natives themselves, living on a very simple diet, are in the main dwarfed in stature, and not noted for longevity. Few specimens of hale old age were met with among them.

The most noticeable effect that I observed produced upon the systems of strangers by the excessive and prolonged heat was simple general debility, a weakening of the bodily functions, marked by a diminution of the assimilative and digestive powers, and resulting in the loss of weight, and anemia. Iron and tonics constituted per force a large percentage of the medicine used in treating the sick. At one time during my stay a chalybeate preparation was needed, and daily used by every lady in the garrison.

The sick report exhibited but little if any evidence of unusual unhealthfulness of the climate; for while the men were not subject to acute disorders, the evidence of a lowering of their physical standard was nevertheless noticeable in their general appearance. Although ostensibly absent, the enemy working insidiously at the foundations of health was really present in

a character as dangerous as that of his more tangible forms. This remark, as my remarks generally, apply to white troops and persons, for both white and colored companies were on duty at the post during my stay; the climate, to the best of my judgment, agreeing with the latter.

Rheumatism and neuralgia stand next in the category of prevalent diseases, and were doubtless the outgrowth of debility and mal-assimilation. Neuralgia of the maxillary branches of the fifth pair was due in some instances to carious teeth; but the majority of such cases could not be traced to such a cause. Tonics and chalybeates were the remedies attended with most success in its treatment.

Several cases of consumption came under my observation. Two were instances of invalids seeking a climate which they thought would be beneficial to them. Both the latter were rapidly fatal. Six cases were local, and two of them terminated fatally during my stay. These facts, and others relative to the climate of which I speak, convince me that it is not adapted to a phthisical patient, or to one so inclined. In fact, I regard it as one of the most unfavorable portions of our country as a sanitarium for consumptives, or even for the weakly and delicate persons who seek a mild and genial place of resort for the winter season. Another circumstance which militates against the adoption of this climate by consumptives during winter, is its variability. Sudden changes from an enervating heat to a temperature nearly, or quite, as low as the freezing-point, take place frequently during the winter months. In my experience, a fall of 40° inside of twelve hours was not an unusual occurrence. Strong winds were frequent throughout the year, and during their prevalence the atmosphere was so charged with fine particles of sand as to be extremely irritating to susceptible lungs. There is little doubt in my mind that this climate has the effect of hastening tubercular deposit, or caseiform infiltration, in persons of a phthisical habit, if not of actually developing consumption *de novo*.

The usual representations of travellers concerning the deleterious effects of alcohol upon the system in health in hot countries, were fully confirmed by its effects upon those addicted to its use at Ringgold Barracks. Any use of alcohol, except as a diffusible stimulant in adynamic forms of disease, or in small physiological quantities, such as found by Anstie to be assimilated by the tissues, was promptly resented by biliary and digestive perturbations and a general lowering of the physical standard. Drinking-men paid speedy and heavy penalty for their excesses—a retribution easily comprehended when we recall the fact of diminished consumption of carbon in the blood, connected with an increased degree of temperature. In a colder climate, this substance, instead of assuming the rôle of a toxic agent, might have been beneficial by conferring needed warmth through the circulatory apparatus. I think alcohol must be regarded as of practically little value as a supporting or restorative agent in hot climates. The idea that its daily use enables the system to resist to any extent the effects of heat, I am satisfied is erroneous, for the reason that the nutritive metamorphoses, already probably diminished by the high temperature, are further retarded by the depressing action of alcohol. A diminution of the cutaneous transpiration, which it is asserted by good authority is caused by alcohol, prevents that evaporation from the surface of the body so vital to comfort in hot climates. I think it may safely be asserted that those addicted to the use of alcoholic spirits show much sooner the marks of age in a hot than in a tem-

perate climate; and that, rather than as a force-generator in hot climates, alcohol acts decidedly as a weakening agent upon the human machine. This is, perhaps, in part explained by the consideration that the system in a colder climate, being invigorated, possesses a greater resiliency and greater powers of resistance. Light subacid dinner-wines were not open to the objections that applied to ardent spirits. I found that claret could be used in moderation without disadvantage, and in some cases with decided benefit.

The increase of bodily temperature which may occur when a native of a temperate climate passes into a hot climate has not been accurately determined, although the researches of Davy, according to Flint, Jr., show an increase in the tropics of 0.5° to 3° . The system, up to a certain point, has the faculty of maintaining a normal equilibrium by evaporation of cutaneous moisture and diminished nutritive changes; but slight variations of health affect the integrity of the system in this respect, and a temperature above blood-heat, acting for months upon the body of an unacclimated person, may sooner or later induce a degree of bodily heat beyond the normal standard—a condition which must influence in a damaging manner the physical functions. My residence at Ringgold Barracks gave me practical illustration of this. Dying the heated term, and when the temperature daily rose to that of the blood and beyond it, a sense of discomfort from abnormal heat oppressed me, coming on after meridian, augmented by the increased circulatory activity after dinner, and diminishing towards midnight. On several occasions, when the heat was unusually high, its effect upon me was similar to that of a febricula, characterized by increased heat of the skin, accelerated pulse, and lassitude.

The effects of heat are by no means identical in all cases. The vigorous resist its effects longer than the feeble. Emaciation, or, at least, loss of weight, occurs as a rule; but corpulence sometimes forms an exception, and persons who are inclined to obesity are not so apt to exhibit the unfavorable effects of a high temperature so soon as the majority of others. This is due, perhaps, to the smaller nutritive wants of persons of this habit of body. Still, the natural tendency to corpulence is apt to be increased in a hot climate from indolent and sedentary habits, and the undue accumulation of fat is fraught with as much danger as the opposite condition. The vital energies suffer in both cases. There may be individuals who, from their peculiar habits of body, can accommodate themselves to the change from a temperate to a hot climate, suffering little or none of those injurious modifications of health which have been noticed as usually produced by such a transition. I cannot say that I ever observed an instance of this kind, although such a case is not more impossible than that of an individual of perfect physical soundness and total exemption from all the ills to which human flesh is heir.

From the nature of my experience, the following conclusions appear to me to be valid:

1st. That certain parts of our country are characterized by climatic conditions, to which, as a rule, the northern native is incapable of adaptation.

2d. That acclimation to malaria is an utter impossibility.

3d. That the unaided heat of a hot climate, acting continuously upon the systems of the natives of temperate climates, exerts, as a rule, a pernicious effect, causing impairment of the functions of digestion, assimilation, and sanguification, inducing more or less anæmia, diminution of the number of respirations, an increase of the action of the heart, loss of weight, pre-

mature blanching and loss of the hair, a decrease of mental and physical vigor, and, to some extent, a shortening of life.

FORT PREBLE, MAINE.

THE COLD-WATER COIL IN INFLAMMATION OF THE EXTERNAL MALE GENITAL APPARATUS—AND AS AN ANTI-PILOGISTIC AFTER OPERATIONS ON THE PENIS.

By F. N. OTIS, M.D.,

PROF. OF GENITO-URINARY DISEASES IN THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK.

THE apparatus here represented, which I have designated the "Cold-Water Coil," is formed of a line of the small-sized India rubber tubing of 1-16 of an inch calibre, and six or seven yards in length. At the middle portion this tubing is coiled upon itself, so that, by half a dozen turns or more, it presents sufficient capacity to loosely encircle the entire penis or scrotum.

This coil, with the length of tubing proceeding from it, forms an apparatus through which, on placing one extremity of the tubing in a bowl or tumbler of ice-water, exhausting its contained air (by suction, or by drawing the tube through the finger), a siphonic current is established through the coil. The discharge-pipe being placed on a lower plane than the water supply, the current may be kept up until the vessel is emptied.

The rapidity of the flow can be regulated either by raising or lowering the end of either tube, which is the simpler plan; but the more convenient one is by a tapering, double silver tube, attached to the discharge pipe, a sponge being fitted to the inner tube. This sponge, when the inner tube is pushed down into the smaller end of the outer tube, becomes compressed and gradually obstructs the flow of water, until not a drop will exude. This contrivance may be regulated so that either a free stream can pass, or that the single drops shall follow each other, more or less rapidly, with the regularity and precision of a time-piece.

By means of this arrangement, I have been able to apply cold to the penis or scrotum continuously and conveniently both to the patient and myself. The coils of tubing are retained in position by a band of cotton or linen cloth. A ready method of constructing this apparatus is by placing a strip of thin cloth, six inches in length and two in breadth, lengthwise, upon

a large speculum or a four or six oz. vial. The tubing, taken at the middle of a piece six or seven yards long, is wound around the vial, and, after the requisite number of turns are made, the projecting ends of the cloth are doubled over the coils and stitched to the under layer between the turns of tubing. If, after completion, the turns are found too small, they may be readily enlarged by drawing the tubing through the cloth to any desired extent.

I have found this simple contrivance of essential service in the acute form of gonorrhœa, reducing inflammatory action promptly, and thus giving relief to painful micturition and erections.

It has proved of great value in keeping down inflammation and in preventing erections after the operation of circumcision. I habitually use it for the same purpose in operations for stricture, and with results more prompt and satisfactory than those hitherto attained by any medication or application, with which I am familiar.

CASE OF CONTINUED (TYPHOID?) FEVER.

By G. PIERREPONT DAVIS, M.D.,

(HARTFORD, CONN.)

On the 9th of September I was called to see a mulatto boy, nineteen years old, who had come to Hartford from Washington, D. C., last June. He had never had intermittent fever, though he was reported by his friends to have had secondary syphilis.

I learned that with the exception of slightly loose bowels for two days, he had been quite well up to the afternoon previous, when, after playing ball, he came in, complaining of headache and weakness.

At the time of my visit he was suffering from frontal headache. His tongue presented a thick, yellow coat; the conjunctivæ were yellow, and though he was not in bed, was quite weak, having no appetite for food. Close questioning produced an admission of slight chilly feelings, but there were neither pain in the limbs, hyperæsthesia, nausea, abdominal pain, or tenderness, nor eruption. The temperature was between 103° and 104°, though the pulse was but little accelerated. I gave the patient about ten grains of calomel, which caused the bowels to move twice.

The next day, September 10, I found him in bed and very weak. Other symptoms were as before, *i.e.*, slight looseness of the bowels, not amounting to diarrhœa; pupils natural; pulse and respiration normal, except a little acceleration of the former. The temperature was 105¼°. Ordered twelve grains of quinine morning and evening.

The next day, September 11, he was much the same, having passed a sleepless night. There were some delirium and frequent and profuse epistaxis, to which latter, however, he is constitutionally subject. The temperature in the morning was 104°, in the evening 106¼°. The pulse was about 120.

September 12.—The pulse is about the same to-day as yesterday, and the temperature in the morning 103¼°, in the evening 105¼°. Efforts to produce sleep since the night of the 10th have been fruitless. Dover's powder, hydrate of chloral, and bromide of potassium in fifteen-grain doses every fifteen minutes have been tried faithfully. The patient is quite delirious, insisting on getting up and dressing. He has been frequently bathed with cold water and alcohol since the fever has been so high. The bowels have moved

every day, occasionally two or three times, with a little tendency to looseness.

September 13.—There is furious delirium, the patient striking his attendants violently with his fists. Aside from this, nothing points to meningeal disease. The temperature is 100¼°, having fallen nearly five degrees since last night. The pulse is less than 100. Still, apart from this, no improvement is apparent. The patient has emaciated strikingly.

This is the first remission that has occurred in the fever since the beginning of the sickness, on the positive assurance of the attendants. He has sweat a great deal, and almost constantly. As he had had no sleep for sixty hours, and the delirium was at this time exceedingly active, I was obliged to exhibit chloroform, and under the influence of this he slept for three hours, and awoke rational and apparently better. In the afternoon, the temperature being 98¼°, he had fifteen grains of quinine.

On the morning of the 14th, I found that the patient had enjoyed a fair night, but was still a little wandering at times. During the worst of the delirium he has had frequent rational intervals. The temperature was 97¼°, and the pulse less than 100.

There have been neither bronchitis, cough, nor hurried respiration; no abdominal tenderness or tumefaction, though on two occasions I detected slight gurgling in the right siliac fossa. He admitted on one occasion some tenderness over the border of the liver. There has been no eruption. The bowels moved yesterday in the evening, the stool being of a perfectly healthy character. The tongue, which has never been dry, is thickly covered with a brownish moist coating. The patient is determined to get up.

In the evening I found that he had slept soundly all day, and sweat profusely, being apparently much better. The pulse was 74, and the temperature 98°. He has had fifteen grains of quinine to-day, both morning and evening.

On the 15th, the temperature was 97°, and the pulse 50. He was sweating profusely, and had had two small and rather loose movements toward morning. Slept well all night, and was still sleeping soundly. To-day he had 7½ grains of the quinine night and morning.

September 16.—From this time he continued steadily to improve.

Sat up on the 16th, and on the 17th the tongue had made considerable progress toward cleaning, a process that was begun on the 15th.

The natural pulse seems to be in this individual about 60.

I enjoyed in this case the advantage of consultation with my friend Dr. Lyon, of this city. The diagnosis, although it at first pointed to typhoid fever, was by no means clear, on account of the rapidity with which the temperature reached a great height, contrary to the rules ordinarily laid down by writers on thermometry, for typhoid fever. We were obliged to exclude meningitis and malarial fever, and so were left in doubt.

Happening at this time, however, to read in the *Supplement to the Medical News and Library* for August, an abstract of Prof. Jürgensen's lecture on the "Slighter Forms of Typhoid Fever," I was struck with the similarity of the cases there described and the one I have just related.

On this account, and from the fact that I have seen none reported in this country, I am tempted to give publicity to the case.

It is perhaps proper to remark, that we are seeing typhoid fever at this time in Hartford with some frequency.

RESECTION CONSIDERED AS A REMEDY FOR ABDUCTION OF THE GREAT TOE, HALLUX VALGUS, AND BUNION.

By ASSISTANT-SURGEON A. C. GIRARD,

U. S. A.

I SELECT the above title for this brief notice, because it naturally calls the reader's attention to the very able article of Dr. A. Rose, of New York, in your No. 200, April 15, 1874, under the same heading. As the merits of the operation are fully discussed in it, I shall confine myself to the report of an additional case operated on successfully after Dr. Rose's method.

Sergeant J. M., *et. 42*, presented himself with an extreme case of abduction of the great toe of the left foot, of several years' standing, with a large and painful bunion, which incapacitated him for duty. In consultation with Surgeon B. J. D. Irwin, U. S. A., this latter drew my attention to the above-mentioned article. I found the subject still further elucidated by the remarks of Dr. F. H. Hamilton, as presented in the Report of the N. Y. Pathological Society, in No. 183, of August 1, 1873. The case appearing in every way suitable for a trial of this mode of cure, and permanent relief being urgently desired by the patient, who was willing to submit to any treatment in order to be relieved from the constant pain and lameness, I decided on operating after Dr. Rose's plan.

Patient was anesthetized with a mixture of equal parts of chloroform and ether. As a line of incision, I selected the space between the *art. dorsalis hallucis* and the *m. adductor brevis*, running from the tarso-metatarsal joint parallel with the axis of the metatarsal bone, about three inches long, penetrating to the bone. The joint was opened and the soft parts around the head of the metatarsal bone detached, taking care not to injure the tendons. Finding great difficulty in passing the chain-saw, as recommended by Dr. Rose, between the metatarsal bones, I made the resection with the curved end of Hey's saw, without accident to the soft tissues, which were protected by retractors. There was no hemorrhage. The wound was sponged out with a five-per-cent. solution of carbolic acid, and the skin united by the interrupted suture up to the cavity left by the removal of the bone, which was left to granulate. The dressing consisted of a small pledget of lint, saturated with carbolyzed glycerine over the wound, and supported with adhesive plaster.

There was no constitutional disturbance; pulse and temperature normal throughout; no pain; no suppuration, and in three weeks the wound had cicatrized, and the patient was able to walk about. He is now, six weeks after operation, returned to duty, and has full use of his foot. This latter is of handsome, classical shape, the great toe slightly shortened; the bunion has disappeared. I took a plaster cast of the foot before operation, and one on the twenty-first day, both of which will be deposited in the Army Medical Museum, in Washington.

So far Dr. Rose's "résumé," as to the practicability, advantages, and safety of the operation has proved correct, with exception of the necessity of after-treatment by submersion in warm water. My patient recovered as soon as any of those reported by him, with barely more treatment than exclusion of air, antiseptic applications, and horizontal position.

WEST POINT, N. Y.

CASE OF

PENETRATING WOUND OF THE ABDOMEN.—PROTRUSION OF INTESTINE—HEMORRHAGE, AND RECOVERY WITHOUT PERITONITIS.

By W. IL. GEDDINGS, M.D.,

AIKEN, S. C.

JOHN McKENNIE, colored, about 34 years old, fell over a wheelbarrow on 13th March, breaking a porcelain tea-cup which he had placed in the loose folds of his shirt. A fragment of the cup was driven through the abdominal parietes, inflicting a longitudinal wound near the median line, and about an inch above the umbilicus, through which a foot of small intestine protruded. Immediately after the accident he walked without assistance to the nearest drug store, nearly half a mile, supporting the protruding intestine with his hands. I saw him half an hour after the accident. He was then cold and pulseless, and was bleeding freely from the mesenteric veins, the contraction of the wound around the protruded mass preventing the free return of the venous blood to the heart, and thus causing considerable engorgement. As soon as the hemorrhage ceased, I proceeded to cleanse and replace the intestine. This was effected without difficulty, and the wound was then closed with the quill suture. In addition to two ounces of whiskey and thirty drops of laudanum administered while closing the wound, the patient was ordered to take a grain of opium every three hours throughout the night.

When I called the next morning the patient had just awakened from a refreshing sleep; expressed himself as feeling perfectly well. Skin natural, pulse strong, and 80 per minute. There was no abdominal tenderness. The opium was reduced to a grain every six hours, and no nourishment allowed except barley-water in small quantities. Within thirty-six hours after the accident the pulse came down to 60 per minute, and throughout the whole period that he was under my treatment there was no perceptible fever. My thermometer being out of order at the time, I cannot state the exact temperature, but am certain that at no time did it exceed $98\frac{1}{2}^{\circ}$ F. The wound was dressed with the usual mixture of carbolic acid and linseed oil. The opium was discontinued on the 18th, and the next day the patient had a consistent stool. On the 27th March, fourteen days after the accident, the wound had firmly united, and the patient was discharged. I have since seen him several times and find that he has never suffered any further inconvenience. The absence of all traces of fever and of peritonitis, although the intestines were necessarily exposed for more than an hour, is the most interesting feature in the case, and so rare as to induce me to present it to the readers of the RECORD.

A CASE OF METASTASIS OF PAROTITIS TO THE BRAIN.

By WILLIAM M. KEMP, M.D.,

NEW YORK.

MARY B—, aged two and one half years, who never had any previous sickness, was seen by me at the Children's Class Northern Dispensary, suffering from parotitis. The disease had been of four days duration. Lin camphora was prescribed with warm bath at night as the child was feverish. Examination of throat and lungs revealed nothing. After using the liniment for twelve hours the swelling of the gland

markedly diminished, but the child became more and more feverish, restless, tossing about in bed, screaming and rolling its head from side to side; it vomited several times and on the sixth day of the disease was seized with a convulsion in which it died. No post mortem examination was permitted. There was evidently a translocation of the disease to the brain, probably in the form of meningitis, Dr. S. J. Radcliff, of Washington, D. C., in a recent communication to the *Philadelphia Medical Times* goes over the literature of the subject, but fails to find cases of fatal metastasis to the brain, save in the experience of Dr. Dickson, of Charlestown, who is said to have seen this fatal complication. We are unable to find a recorded case of parotitis, with death resulting from metastasis to the brain. Authors speak of its possible occurrence but none quote from actual experience.

237 W. 23d STREET, N. Y.

Progress of Medical Science.

LETZERICH ON LOCAL AND GENERAL DIPHTHERIA.—Letzerich has recently published his views on this subject, which have special interest, as he is one of the boldest defenders of the parasitic theory of diphtheria, and has contributed some very important data for the support of his views. He states his belief as follows: Local diphtheria is a contagious disease of the mucous membrane. The *contagium* consists of a fungous vegetation which goes through its development and growth in the diphtheritic exudation, and in the tissue of the mucous membrane if there is no exudation. Should these low organisms force their way into the circulation they spread and increase in the body, and work a general infection, *i.e.*, general diphtheria.

These low organisms, which he classes as bacteria, plasma spheres and micrococci, etc., induce various changes both primarily in the local foci of the disease, and secondarily in such organs as the kidneys, spleen, liver and heart. First come disturbances in the nutrition of the tissues themselves, from the occurrence of fungous emboli; these interfere with the circulation, and then an astonishing increase in the fungi takes place. With the increase of the micrococci *pari passu* a destruction of the cellular elements, so that the cells of the kidneys, liver and spleen may disappear, as well as the contractile substance of the cardiac muscle.—*Virchow's Archiv.*, 4, 1874.

LUNG AFFECTIONS AMONG THE WORKERS IN THE ENGLISH POTTERIES.—Dr. Ballard writing to the *Practitioner* gives an interesting report of some of the diseases that prevail among the pottery workers, in two towns of Staffordshire, England. In one town 312.5 per 1,000 of the male inhabitants over 20 years of age are engaged in this industry; in the other 268.8 per 1,000. In the former town, of the women, 177 per 1,000 over 20 years of age, and in the other 109.5 per 1,000 are similarly engaged. Taking the period between the years 1861 and 1870, and comparing the mortality of these operatives, from lung diseases, with the general mortality in all England, from the same causes, he found that while the ratio of deaths between the operatives from the ages of 15 to 25, including males and females, was lower than among the general population, from the ages of 25 to 45, the proportional number of deaths was somewhat higher; noticeably so among the males, between the ages of 45 and 55, and very markedly so from the ages of 55 to 65. During the last decennium the comparative mor-

tality of the females under 55 years had diminished which is thought to be due to the favorable influence of recent legislation in placing restrictions upon the employment of young women under certain ages. In this industry, the operatives are constantly in an atmosphere which is filled with dust, and the great objections to it, from a sanitary point of view, are that the particles of dust, the lead glazes and lead colors are inhaled, and then, besides, the work places are hot and badly ventilated. Substantial improvements have been made in the large factories that have recently been built.—*Rundschau*, Oct., 1874.

THE RELATION BETWEEN KIDNEY AND HEART DISEASES.—Dr. Galaban, of London, has made some researches to see whether he could discover what changes in the vascular system accompanied the granular kidney, and whether similar changes are found in other forms of renal disease. The following are some of the facts he ascertained with the interpretation he makes of them. In sixty-six cases of pronounced granular diseases of the kidney, there was hypertrophy of the heart in all except ten cases, and the left ventricle was most frequently hypertrophied; he did not find that the hypertrophy was more marked in young persons. In about half the cases of tubal nephritis the heart was hypertrophied, but in complicated cases of fatty kidney there was only a single case of hypertrophy. He states, in conclusion, that hypertrophy of the left ventricle occurs chiefly with granular kidney; tubal nephritis is also often connected with hypertrophy of the heart, but the renal disease is usually then of long continuance.—*Rundschau*, Oct., 1874.

EXPERIMENTS ON AMMONIEMIA AND THE REACTION OF THE URINE.—Feltz and Ritter, of Nancy, have performed a very large number of experiments on the urine, and have arrived at some conclusions which are somewhat at variance with those usually entertained. They state that as a general thing albumen and albuminous substances produce the ammoniacal fermentation. Two experiments were performed on dogs to test the change that takes place in the urine during retention in the bladder and urethra. By a careful adjustment of mechanical pressure they succeeded in retaining the urine for over two days in the bladder and also in the urethra. They found that in the former it did not become ammoniacal, while in the latter this change soon took place. In one of these cases they found bacteria in the bladder. They also filtered some putrescent urine and suspended the filtrate in a weak solution of urea and allowed it to become ammoniacal. A catheter was then dipped in this solution or in a solution of putrid urine, and introduced into the bladder, but the ammoniacal change did not ensue for some time. If, however, blood was introduced into the urine alkalinity was immediately detected. Injections of urea and carbonate of ammonia into the veins confirmed the experiments which have frequently been made showing that urea is harmless, while carbonate of ammonia is noxious. So, too, solutions of urea mixed with the ferment solutions already mentioned were injected into the blood but without any injurious effect. When large quantities of this solution were injected there was an increase of temperature, abundant diarrhoea, followed by death, which the experimenters ascribed to septicæmia.—*Journ. de l'Anat. et de la Phys. Allg. Med. Central Ztg.*, 87, 1874.

THE UNFAVORABLE INFLUENCE OF CERTAIN HEART AFFECTIONS ON PREGNANCY.—The influence of pregnancy in causing a physiological hypertrophy of the heart, especially of the left ventricle, is well

known. Bottenhuit, after alluding to this fact, reports a striking case of mitral stenosis and insufficiency combined, which ended fatally three days after delivery, at the sixth month of pregnancy. In connection with this case he quotes the opinions of Sæe on the injurious influences of heart affections upon the course of pregnancy and the life of the fœtus. He thinks that aortic insufficiency generally exercises no special influence upon pregnancy; women so affected often having borne several children, and not suffering from œdema or dyspnoea. Stenosis of the mitral orifice will not influence pregnancy unfavorably unless accompanied by congestion of the lungs or œdema of the lower extremities.

In the first and second cases, therefore, marriage need not be forbidden. In mitral insufficiency the physician should strongly discountenance marriage, especially when congestion or stasis already exists in the lungs. Under such circumstances pregnancy is a very dangerous condition to the mother, because it is likely she will have fresh attacks of endocarditis. The life of the fœtus may also be sacrificed through the faulty character of the maternal blood, for it will be incompletely arterialized, owing to the cardiac difficulty.—*Allg. Med. Central Ztg.*, 78, 1874.

SUBCUTANEOUS INJECTION OF ERGOTIN IN FIBROMATOUS AND MYOMATOUS TUMORS OF THE UTERUS.—Hildebrandt, in an article on this subject, quotes the experiences of Scanzoni, Burow, Hennig, and Keating with his own, which has also been extensive. He concludes that we have the most favorable conditions for the absorption of a fibroma or myoma of the uterus under the ergotin treatment, (1) when the growth is firm and elastic, (2) when its seat is submucous, (3) when the uterine walls are healthy, contractile, not thinned by overdistension, not rendered rigid by exudations, and when no inflammatory processes are going on in the neighborhood. He finds that the solution of ergotin is most efficient and least likely to set up inflammatory action when it is prepared according to Wernich's directions; he adds a few drops of glycerine to keep it from moulding.—*Allg. Med. Central Ztg.*, 83, 1874.

TREATMENT OF CYSTIC TUMORS OF THE THYROID GLAND.—At a recent clinic at the Hôtel Dieu, at Paris, M. le Dentu presented a case of cystic tumor of the thyroid gland, on which he proposed to operate, but before doing so he gave a very good description of the malady, and pointed out the dangers attending it, whether operated on or not. In referring to the treatment, operative measures, he said, offered the only chance of cure, as medication had been of no avail in stopping the progress of the disease. Punctures with a bistoury, or even with a trochar, he condemned as being dangerous, and even small, repeated punctures are not free from danger, as suppuration may take place, or the blood putrefy, and thus endanger pyæmia or septicæmia, which almost always ends in death. The same objections apply to setons or drainage tubes. Incising the cyst, and then filling it with charpie, as practised by Celsus, is also a dangerous proceeding, as it may be followed by hemorrhage or unhealthy suppuration. Excision, even partially, ought not to be thought of, as being a vascular organ the operation may end in fatal hemorrhage or phlebitis. Removal of the tumor by caustics will not expose the patient to such danger, and among these he preferred the chloride of zinc, as used by Maisonneuve in the form of darts. Injecting the tumor with irritating substances was the least objectionable form of practice. He did not approve of injections of wine, and gave the preference to the tincture of iodine, in the proportion of one part to

three parts of water, as for hydrocele, though in some cases it may be necessary to use it pure, as he had seen it done by Nélaton. This surgeon sometimes added iodide of potassium to iodine; sometimes to saturation, for injecting tumors of this sort.—*Irish Hospital Gaz.*, Oct. 15.

THE PHYSIOLOGICAL ACTION OF APOMORPHIN.—In a paper on this subject, read at a late meeting of the Paris Académie des Sciences, by M. David, the author related the results of a long series of experiments relative to the physiological effects of the chlorhydrate of apomorphin. The preparation used by him in his experiments was obtained from the chemist Duvernoy, of Stuttgart, and was administered in the form of the subcutaneous injection. Though this solution in water changed color, its properties were unaltered, and remained in a perfect condition for some weeks. This preparation brought on vomiting when administered in the following doses: In a dog the vomiting came on five to six minutes after the injection of two milligrammes of the apomorphin, and was preceded by a very short period of nausea. The animal showed no symptom of disturbance. The dose necessary to produce vomiting in cats was much larger, and appeared to vary in the case of different animals. Thus, in one cat vomiting was brought on after the injection of two milligrammes (.03 of a grain), while another required a dose of thirty-three milligrammes (half a grain) to produce the same result. Pigeons required a minimum dose of four milligrammes (.06 of a grain) before they were sick. Experiments made on three or four occasions, on subjects in Dr. Revillod's wards, produced vomiting with a dose of from three to four milligrammes. The vomiting came on in six minutes after the injection, and was only preceded by a slight feeling of uneasiness and giddiness immediately before vomiting. The sickness itself came on suddenly, and recurred three or four times; the patients soon recovering from its effects. Chlorhydrate of apomorphin produces in certain animals, such as cats, pigeons, rabbits, rats, and guinea-pigs, a special excitement which, M. David thinks, may be attributed to a specific action of the apomorphin on the nervous centres of the animal.

ECZEMA OF THE BREAST COMPLICATED WITH SCABIES.—Hardy, in an article in *L'Union Méd.*, for September, 1874, considers the rule a general one, that eczema of the breast only occurs under three distinct conditions: (1) During pregnancy; (2) during lactation, or (3) in the course of scabies. In cases, therefore, where a woman has this affection, who is neither pregnant nor nursing, Hardy always suspects scabies, and in the large majority of cases the suspicion has proved to be well grounded. The eczema may remain for a long time after all the mites have disappeared, and he had seen a case where this condition existed after the lapse of eight months. It may also be the result of eczematous eruptions on other portions of the body; as on the face, for example. In these cases he recommends the seemingly remarkable plan of curing the eczema first and the scabies afterwards, because the remedies by which the latter disease is relieved, have the unpleasant effect of irritating the eczematous parts, and thus prolong the period of healing.—*Ugeskrift for Læger*, October, 1874.

CARBOLIC ACID IN THE TREATMENT OF TAPE-WORM.—Dr. Bell relates the following case, which is substantially as follows: A patient came to him to be relieved of a tape-worm. Kousoo and male-fern root had been tried in vain. A single dose of turpentine

was given, but it only resulted in producing a severe irritation of the stomach. Fluid extract of male-fern was next tried for several months, but with no better success. Finally, a purgative was ordered, and then carbolic acid, freely diluted with water, was given four times a day. Two days after this latter treatment was commenced several links of the tape-worm were expelled. The form of the remedy was then changed to pills, and about two grains of the acid were given every hour. Long fragments soon came away, and on the third day the head and four feet of the worm were discharged.—*Boll. d. Sci. Med.*, Oct., 1874.

TREATMENT OF HOOPING-COUGH.—Wilde claims that he can cure every case of whooping-cough within eight days by the following treatment: The patient is not to leave the room, and at every access of coughing is to hold before his mouth a small piece of cloth, folded several times, and wet with a teaspoonful of the following solution: ether, 60 parts; chloroform, 30 parts; turpentine, 10 parts.—*Deutsches Archiv. f. Klin. Med., Allg. Wien Med. Ztg.*, 45, 1874.

ERGOTIN IN CROUPOUS PNEUMONIA.—Dr. Wycisk, acting on the principle that this drug contracts the vessels and so prevents exudation from them, has treated six cases of croupous pneumonia in this way, and gives the following report: In one such case, marked by an excessive highly albuminous expectoration, it ceased entirely two hours after the administration of the drug in powders of nine grains each every quarter of an hour. The abundant râles in both lungs soon diminished, so that there was only a slight crepitation at the original focus of the disease. These good effects lasted for two days. Two relapses occurred, however, but the same good effect was again obtained by the administration of the ergot. After the second relapse, ten drop doses of the tincture of ergot were given four times daily, until convalescence was fully established. In the five other cases the ergot was used early, and none ended fatally, none became chronic, and none left appreciable deposits behind them; in all of them the exudation was decidedly checked by the ergot. It is, however, held to be a dangerous remedy when the lungs are considerably infiltrated, where there is emphysema, where the cerebral arteries are weak, and where the patients are feeble or decrepid.—*Allg. Med. Central Ztg.*, 88, 1874.

THE LOCAL APPLICATION OF BROMINE IN THE TREATMENT OF CARCINOMA OF THE CERVIX.—Henneberg has found that the alcoholic solution of bromine when used in the proportion of one to five, is a useful application in cancer of the neck, both in the treatment of the open wounds produced by the exfoliation of the growth, and also when injected into the substance of the diseased tissues. This is essentially the plan of Schroeder. Under the guidance of Steek, the author performed some experiments to decide what the action of this solution actually was upon growths that had been removed. He obtained portions of a typical case of schirrhous and placed them in the bromine solution for forty-eight hours. They were then removed, and on examination seemed to consist merely of traces of connective-tissue with spindle cells. In another case the cancerous masses were observed to almost wholly disappear under the action of the solution.—*Allg. Wien. Med. Ztg.*, October, 1874.

SUEVERN'S DISINFECTANT.—The component parts of this solution are lime, chloride of magnesium, coal-tar and water. Haussmann's experiments have shown that lime, of itself, is able to clarify the turbid contents

of sewers, while it retards the development of infusoria and fungi until the tenth day. The strong ammoniacal smell which follows its use may be overcome by adding one part of the chloride of magnesium to ten parts of the lime. The development of the low microscopic organisms are retarded for a much longer time by the further addition of tar.—*Geigel's Offentl. Gesundheitspflege*.

THE CONTENTS OF SEMINAL CYSTS.—Cazeneuve and Duremberg have recently examined three seminal cysts and report that the spermatozoa which were found in the fluid after filtration exhibit active movements for more than twelve hours after removal from the cysts. The fluid had a weak alkaline reaction, and contained a considerable quantity of common salt, only slight traces of which are present in the normal fluid of the seminal vesicles. On the other hand, the phosphates were wholly wanting, while they are commonly present under the form of the phosphate of magnesia.—*Allg. Wien Med. Ztg.*, 45, 1874.

THE LOSSES IN THE FRENCH AND GERMAN ARMIES DURING THE FRANCO-GERMAN WAR.—It is stated on the authority of Dr. Chenu, Inspector-General of the French Army, that the French losses in the late war in killed, missing, and from wounds and disease, reached a total of 138,871. The number of wounded was 142,000; the number of those who were incapacitated on the march was 1,421; the missing amounted to 11,914. There were 2,881 officers among the dead, and 96 among the missing. Chenu observes that the German loss was only 44,000 killed, and 127,000 wounded, and ascribes the great disparity in the two armies to the deficiencies in the French field hospitals, adding that in this war, as well as in the Crimean and Italian campaigns, a much larger number of the military died of disease in hospitals than perished outright on the field of battle or died subsequently of their wounds.

This statement, however, is denied by Liefermeister so far as the last war is concerned, for he says "that the number of deaths from disease were far fewer than the number of deaths from external violence," and he ascribes this unprecedented fact to the advances which the science of public hygiene have made in our time.—*Allg. Med. Central. Ztg.* 93, 1874.

SURGICAL ASSISTANCE AT HOME.—A most distinguished and competent body of medical men in Paris—those attached to the *bureaux de bienfaisance* of the city—has taken up and is now engaged in discussing the question of the high mortality in the surgical and lying-in wards of general hospitals, and the possibility of establishing a system of surgical assistance at home, which would diminish overcrowding and loss of life through infection in hospitals. . . . There is a general feeling amongst medical men that surgical operations, especially the major ones, are altogether impracticable in the houses of the poor, and that all cases calling for surgical interference must be sent to the hospitals, so that, while the plan of relieving medical cases has succeeded very well, scarcely any surgical assistance is given at home. It is against this view that the medical men of the *bureaux de bienfaisance* are contending. At a meeting of the association recently held, the plan received the approval of Drs. Boimet, Passant, Dusseris, and Berrier. M. Dusseris gave a long list of important operations which had been successfully performed at the homes of the poor.—*The Correspondence of The Lancet*.

THE ARMY MEDICAL STAFF BILL.

THE question of increasing the rank of the medical officers of the army again becomes of interest in connection with the bill recently presented to Congress by the Committee of the American Medical Association. In its general spirit it does not differ from a bill presented for a similar purpose and by a similar committee last year. There are but few points of issue in the case; in fact, the efforts which are now being made to secure the passage of the bill are founded mainly upon the conviction that particular injustice has been done to the medical staff by the passage of the act of June 23, 1874. The profession meekly asked for bread, but in its stead received a stone.

Instead of rewarding the old officers by increase of rank and pay, instead of encouraging the younger officers by reasonable chances for promotion, the act in question actually reduced the number in the medical staff, thereby placing an extra barrier to advancement for those who still remained in service. For instance, by that act the number of assistant medical purveyors was reduced from four to two, and the number of surgeons from sixty to fifty. At the time the law was passed, there were fifty-three surgeons actually in service. In order, however, to be relieved of the responsibility of mustering the extra number of surgeons out of service, the legislators very magnanimously allowed them to remain. This was no doubt a great effort on their part, and showed a consideration for the services rendered by these surgeons which it is to be hoped the profession will not be slow to appreciate. There was so much generosity in the whole proceeding, that so far from being commonplace, it rises to the level of the affecting. So far, so good; it was really more than the poor but worthy surgeons had, under the circumstances, a right to expect. In order, however, that this show of kindness to the surgeons should not prove "prejudicial to the service," that the provisions for promotion should not be mis-

construed or misinterpreted by greedy aspirants at the other end of the line, it was to be specially understood that until the fifty-three surgeons should be reduced by death or resignation to fifty, no one below the rank of major should hope to rise. And this is the way that our last Congress answered the earnest, respectful, and reasonable appeal of the whole profession of the country!

An extra hindrance to the promotion of the assistant surgeons, is the fact that their number, as fixed by law, is three times greater than that of the surgeons. The army medical staff is not only at a stand-still as regards any increase of rank or pay; but, worse than this, is actually degraded in comparison with every other department in the army. These are facts which the profession must take into account in its coming struggle for justice to its representatives in the army.

The following is the Bill now being urged in Congress; and for the better appreciation of all its provisions, we give it in full:

"Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled: That hereafter all the officers of the medical corps of the army now known by law as surgeons and assistant surgeons shall be designated surgeons, and that they shall have rank and promotion in accordance with length of service as follows, viz.:

"Surgeons of less than five years' service shall have the rank, pay and emoluments of first lieutenants of cavalry; surgeons of more than five and less than thirteen years' service, the rank, pay and emoluments of captains of cavalry; surgeons of more than thirteen and less than twenty-three years' service, the rank, pay and emoluments of majors; surgeons of more than twenty-three and less than thirty years' service, the rank, pay and emoluments of lieutenant-colonels, and surgeons of thirty years' service and upwards, the rank, pay and emoluments of colonels; *Provided*, That nothing in this act shall be construed to increase the total number of medical officers now authorized by law.

"SECTION 2. That nothing in this act shall be construed to permit the appointment of any person in the medical department until he shall have passed the examination now required by law, and that the second examination now required of all medical officers before promotion to the rank of surgeon shall hereafter be required of all medical officers before promotion to the rank of major.

"SECTION 3. That all laws and parts of laws inconsistent with the provisions of this act be and the same are hereby repealed."

It will be seen that the intention is to abolish the office of assistant surgeon in the army. This is entirely in accordance with a proper understanding of the respective duties of surgeon and assistant surgeon. Practically, there is no difference whatever. We have seen this during our late war, and see it in the every-day routine of office or out-post duty. Frequently, in the care of a post, the assistant surgeon replaces the surgeon, and *vice versa*. Indeed, not to make the comparison invidious, the majority of responsibilities and the greater part of the really scientific labor has been performed by the assistant surgeons. As striking exam-

ples of the truth of this assertion, we have but to refer to the valuable labors of Woodward in the Army Medical Museum; Otis, in the medical and Surgical History of the War; Billings, in the library of the Surgeon-General's office; and Harvey Brown in his Reports on Quarantine. In the management of our general hospitals, the assistant surgeons performed all the necessary duties to the entire satisfaction of their superior officers, and no difference was made except in the matter of rank and pay. The request of the committee is not only modest and reasonable, but it is eminently just to a large number of very capable, earnest, and trustworthy young men.

The proposition that these gentlemen shall have rank and promotion in accordance with length of service, is the only one which can be entertained by the profession as offering the best opportunity of fixing a basis for the reward of true merit. Such a plan would not only stimulate those in the corps to fulfil all the conditions required to induce them to remain, but would be very likely to tempt some of the best of our freshly graduated men to enter the corps.

When we prospect the results, if the bill should become a law, we are surprised at the amount of good it would effect to the corps and to the profession at large in comparison with the small amount of expense to the government. By the provisions of the act, but ten surgeons would be promoted to the grade of colonel, half of which number would probably resign; but fifteen surgeons would be promoted to the grade of lieutenant-colonel; and but seventeen of the present assistant surgeons with the rank of captain would be promoted to the grade of major, making only fifty-four majors in all. Even allowing for the retirement of none of the older members of the corps, the whole number of those ranking as major and upwards would only exceed by three the number of medical officers of corresponding rank in the navy. We have thus far given in outline the merits of the question, in order to prepare the way for fuller discussion in future numbers.

SCHOOL HYGIENE.

It is only in keeping with the previous stupid conceit of the School Board that no heed has been taken to the suggestions of the press in regard to the necessary reform in school hygiene. Medical men of high authority over the land are of one opinion as regards the necessity for fresh air, good light, plenty of room, perfect drainage, and protection against contagious diseases in our class-rooms, and yet a School Board, which should be the representative one of the country, maintains a defiantly dignified indifference. There is hardly a grammar-school in the city which, on inspection, cannot be shown to be in a very unsanitary condition—a condition which cannot be improved by suitable sanitary regulation. The Commissioners dare not claim to be ignorant of this state of affairs. Instead of reforming the abuses, they go on crowding the school-rooms with a seeming determination to

prove to sanitarians how badly our poor school children can be treated, to what an extent their hygienic requirements can be curtailed and life be preserved. By and by the community will be thoroughly waked up to the necessity of calling these functionaries to an account, and then some change for the better may take place. We believe that we are approaching this crisis, that the time is not far distant when the public, in the interests of the rising generation, will demand that the medical profession be represented in the board, and that sanitary inspection be re-established.

VIVISECTION IN ENGLAND.

At the meeting of the British Medical Association, held at Norwich, England, the agents of the Royal Society for the Protection of Animals, with more zeal than discretion, objected to some vivisection experiments. The experimenter was Dr. Magnan, a French physiologist, who wished to show the difference in the effects of alcohol and absinthe in high doses when injected into the veins of dogs. Permission to perform the experiment was denied him by the committee; but not respecting the squeamish sentimentality of that body, he concluded to carry out his demonstrations before a select audience. The dog in whose veins alcohol was injected presented all the symptoms of intoxication, but recovered; the one who was subjected to the injection of absinthe was soon seized with epileptic convulsions, and died.

We do not wish to say that these experiments proved a great deal, but desire to refer more particularly to the principle which the Humane Society afterwards attempted to establish. That Association, in the line of its presumed duty, wished to test the legality of this experiment, and brought the question into an English Court. After the hearing of testimony on both sides the complaint was very summarily dismissed, on the ground that legitimate scientific experimentation did not come under the liberal interpretation of the law. We commend this case to the serious consideration of our own Society for the Prevention of Cruelty to Animals, in the hope that it may modify their enthusiasm during their prospective crusade against the "cruel doctors" in the present State Legislature.

EASTERN DISPENSARY.—The annual meeting of this institution was held on Monday evening, the 4th inst. The following facts were reported: Yearly receipts, \$4,350.50; expenses, \$4,041.90; number of patients treated, 22,676; number of patients vaccinated, 3,144; prescriptions dispensed, 31,712; patients treated at dwellings, 2,623; patients treated at dispensary, 20,053; sent to hospital, 677; died, 105. The following trustees were elected for the year: Robert R. Crosby, William Dennistoun, John W. C. Leveridge, Jared Macy, Josiah Macy, Jr., Russell Raymond, Samuel Raynor, Edward C. Sampson, William R. Thurston, Jr., Samuel T. Valentine, Isaac P. Wood, John T. Willets, John H. Waydell, Aug. W. Weismann, Julius Frankel, M.D., Noble Heath, Jr., J. C. Roderiques, Edmund A. Hurry.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Dec. 9, 1874.

GENERAL MILIARY TUBERCULOSIS AND ENDOMETRITIS.

DR. KNAPP, PRESIDENT, in the Chair.

DR. MARY PUTNAM-JACOBI presented specimens removed from the body of a woman, aged 31 years, who died at the Woman's Infirmary. In the month of March last the patient had a normal confinement; but the child, which was her fourth, had died shortly after. From that time the mother's health failed gradually and steadily. In September she had a miscarriage, after which she failed still more rapidly. The first definite symptoms that were ascertained, dated from a week before the time Mrs. Jacobi saw her. At that time the husband stated that she had a slight twitching, with partial loss of consciousness. These attacks occurred several times during the evening of that day, and at irregular intervals for a few successive days. After these attacks she became partially stupid, but the husband said she had no fever. When Dr. Putnam-Jacobi saw her she was lying in a semi-comatose condition, could be aroused, and would answer some questions. Made no complaint of pain, but pressure upon the right iliac region caused her uneasiness. Her general sensibility was somewhat diminished, but was by no means gone. There was no paralysis anywhere, no change in the iris, and she could protrude the tongue when fairly roused. With the partial loss of consciousness and sensibility there was some fever. The temperature was said to have been 103° F., but towards the last it fell to 99° F. Upon percussion the spleen was normal; the liver gave a small area of dullness anteriorly, in consequence of being crowded upwards by tympanites. There was nothing abnormal in the heart or lungs. Chronic metritis dated from her miscarriage in September; but no examination was considered necessary. The diminution in consciousness gradually increased, and deepened into complete coma. The urine was carefully examined, but there was neither albumen, casts, nor blood. Under the circumstance a diagnosis of encephalitis was made. Without presenting any new symptoms, the patient died in the course of a week afterwards.

At the *autopsy* the evidences of encephalitis were plainly marked, in the shape of adhesion of the membranes to the cerebral hemispheres along the superior longitudinal sinus. In other places, instead of this complete adhesion, there were little masses that were evidently tuberculous. Some of these existed on the left side of the brain, and also in the pia mater over the base of the brain. There was also quite a large amount of effusion in the ventricles. The surface of the brain was injected, but there was no suppuration anywhere. Besides these lesions there was an extensive deposit of miliary tubercles, occupying nearly every organ of the body. A great many of these tubercles occupied the lungs and spleen; very few were in the liver; none in the kidneys, while they were scattered in greatest profusion over the peritoneum, and were most abundant in the peritoneal fold of the uterus. The Fallopian tubes were distended with a cheesy mass consisting of small lymphoid cells. The cavity of the uterus was in a state of complete fungous degeneration.

The case was of especial interest from three points of view. 1. General miliary tuberculosis developing in connection with endometritis, and evidently starting from the cheesy degeneration in the Fallopian tubes as a focus. (The lymphatic glands of the abdomen, unfortunately, were not examined.) No tubercles were discovered in the cavity of the uterus on cursory examination. 2. The existence of subinvolution without any increase in muscular fibre. So far as examined, the hypertrophied tissue consisted of conjunctive elements, with numerous rounded and nucleated cells, some flat, and a good deal of cylindrical epithelium. Immediately under these granulations the fibres of the uterus were very distinctly seen, separated by an immense quantity of lymphoid cells. This condition extended half-way through the thickness of the uterine wall. 3. The question of diagnosis of general tuberculosis.

SUPPURATIVE INFLAMMATION OF THE INTERIOR PARTS OF THE EYE, CAUSED BY A GUN-CAP.

DR. H. KNAPP presented an eyeball and made the following remarks:—Last Friday, between 9 and 10 o'clock in the evening, I was called to examine a lady's eye, which sixty hours previously had been struck by a gun-cap sprung from a toy-pistol her son had fired from a distance of about five feet. At the moment she felt sharp pain, and tears and blood ran from her eye; but for two days she noticed no particular inconvenience from that eye, and could see well with it. Forty-eight hours after the accident the eye commenced to become painful and weak. When I saw it, the pupil was narrow, the interior could be illuminated with the ophthalmoscope, but the details of the fundus were not recognizable. She counted fingers at a distance of four feet. The lower part of her visual field was slightly contracted. There was a small penetrating wound in the upper margins of the cornea and iris, through which, I had no doubt, the gun-cap must have entered. The anterior chamber was complete. Pressure upon the upper part of the sclerotic was painful, not on other parts. When firing, the boy had held the pistol down. From these symptoms I concluded that the gun-cap was situated in the upper part of the retina. As I could not see it, I had atropine instilled into the eye; the pupil dilated only little during an hour. I ordered six leeches to the temple, and the instillation of atropine every twenty minutes during the night. The next morning the pupil was larger, but fundus less red when looked at with the ophthalmoscope. Dr. T. R. Pooley, who met with me in consultation, thought there was a faint chance of extracting the foreign body. On the request of the family, we delayed the operation until 1 P. M., to have the advantage of consulting with Dr. H. B. Sands and Dr. Schirmer. At 1 P. M. the inflammation had so much advanced that the fundus could no longer be illuminated; there was chemosis, and the patient saw only the movements of the hand. Under these conditions we all thought that only the removal of the globe without delay was left. It was done while the patient was etherized. No unpleasant symptom occurred, and the wound healed *prima intentione* as usual.

I opened the eyeball two hours after I had extirpated it. It showed the finest specimen of recent suppurative inflammation of the inner structures of the eye that I have ever seen. The vitreous was streaked with pus; in the posterior half of the globe there was marked congestion. The retina was transparent, but its vessels were engorged. On the posterior face of the iris, corresponding to the wound, was a small ab-

scess. The lens was transparent and uninjured; the ciliary body showed no notable lesion. A bright, yellow, thin piece of metal, about $1\frac{1}{2}$ lines in length and 1 line in breadth, lay in the retina, above $2''$ inward from the horizontal meridian, and $1\frac{1}{2}''$ behind the ora serrata. The retina was everywhere in its normal position.

From this condition I may, without appearing too sanguine, draw the conclusion that the piece of gun-cap could have been extracted and the eye saved if come under observation before the inflammation had darkened the interior, that is, during the first forty-eight hours after the accident. Under the guidance of the ophthalmoscope I would have made a meridional opening through the coats of the eye, in the immediate vicinity of the foreign body, and endeavored to extract the piece of metal by means of a blunt, curved, and grooved hook, such as I have devised for that purpose. In a few operations of this kind I have been successful.

WHITE SARCOMA OF THE CILIARY BODY.

DR. KNAPP exhibited another eyeball which he had removed that day from a man of about forty-four years of age. The patient had formerly been under the care of Dr. D. R. Gebser, at the N. Y. Ophthalmic and Aural Institute. When he presented himself for the first time, the eye had the appearance of "serous irido-choroiditis." The fundus was visible, the visual field complete, the vision impaired. This inflammation soon assumed a graver character, pus appeared in the anterior chamber, the vitreous became dark, panophthalmitis set in, the sclerotic burst, and pus escaped. There was a remission of the symptoms for a few months, but recently, the eye becoming more troublesome again, the patient consulted Dr. K., who advised, and a week later performed, enucleation.

There was pus, and dark puriform fluid, probably the result of hemorrhage, in the posterior part of the globe, whereas the anterior portion was occupied by a soft, white sarcoma springing from the ciliary body and covering completely the posterior surface of the lens. This growth, in all probability, was the original disease, which, entering into the second—"glaucomatous"—stage, produced the symptoms of serous irido-choroiditis advancing to purulent irido-choroiditis, with perforation and temporary shrinking of the globe.

This observation demonstrates how judicious it is to seek for a complication—a primary disease—in all cases of purulent irido-choroiditis that are neither of a traumatic nor metastatic—pyæmic—nature.

PERFORATION OF APPENDIX VERMIFORMIS, PERITONITIS AND DEATH.

DR. BRIDDON presented a specimen of the above, with the following history:

I did not see this case during life, and am indebted to the attending physician, Dr. Hadden, for particulars of the symptoms which presented themselves. The patient was a young lady, fifteen years and ten months old, menstruating. November 25th she came home complaining of abdominal pain, and sensations of chilliness, and disposition to vomit. Dr. H. saw her on the morning of the 26th. She was then vomiting, suffering intense pain in the lower part of abdomen—in fact, the ordinary symptoms of peritonitis. Temperature was not noted; pulse was seventy-four. After the day on which her physician visited her there was no more gastric disturbance; pulse steadily rose in frequency, and on the fourth day was one hundred and thirty and forty. Moderate tympanites was pres-

ent; the pain was diffused over the whole abdominal surface. On the 30th Prof. Budd saw the patient in consultation. Probabilities of hæmatocele and perforation were discussed, but the tympanic condition masked the local mischief. There was no doubt as to the existence of universal peritonitis, but the precise nature of the cause was undetermined, or rather the differential diagnosis between the two suspected lesions was not made.

The symptoms gradually increased, and she died on the 3d day of December, eight days from the first manifestation of illness.

Dec. 4th, 10 P.M.—Thirty-seven hours after death, body frozen. Abdomen moderately distended, and resonant on percussion; cavity free from fluid effusion; omentum covering all the hollow viscera, nowhere adherent to abdominal walls, save at a point situate in the right iliac fossa. It was, however, everywhere adherent to the distended small intestines; adhesions were evidently recent, and easily broken down; the exudation was not in excess, being only sufficient to agglutinate opposing serous surfaces. In the right iliac fossa the exudation was of a firmer character, but there was no fluid extravasation, either purulent or feculent; colon was collapsed, small intestines inflated, and highly congested near their termination in the cæcum. The latter organ and processus vermiformis were hid from view by the adherent omentum. On carefully separating these parts the processus was found of a dark violet hue; its apex was destroyed by gangrene, and the margin of the truncated extremity was fringed with the flocculent débris of tissue. Half an inch from the extremity was another perforation, about three lines in diameter; on the proximal side of this latter perforation was a concretion resembling a date-stone in color and conformation, but of much smaller dimensions; it measured three-eighths by three-sixteenths of an inch in its diameters.

The corpora fimbriata were in a highly hyperæmic condition—swollen, tumid, and of a dark maroon color; there was a perforation on the surface of one ovary, leading into the cavity of an ovisac, filled with a dark clot.

Remarks.—I have to regret my inability to present the foreign body that occasioned all this mischief; but it was unfortunately lost by the gentleman who took charge of it. It was my intention to make a section to determine its nature. I am not prepared to say what it really was. It was our general impression that it was a seed. I do not think it was an enterolith; but of course its nature must remain uncertain. I was surprised at the very small amount of effusion; fluid there was none; the serous surfaces being simply sticky when separated from each other. Even the amount of exudation in the immediate neighborhood of the lesion was simply sufficient to mat the parts together. There was nothing that could have been detected by manipulation during life.

MADAME LETITIA RATAZZI, one of the members of the Bonaparte family, has for some months been visiting the principal towns of Europe, to study the ways and means of establishing a hospital which shall be especially devoted to the treatment of cancer. As is well known, several members of the family have succumbed to this disease. The first deposit will be 150,000 francs, to which will be added a biennial prize of 5,000 francs for the best work on the subject, as well as a sum of 20,000 francs for the one who shall describe a true cure for cancer.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 17, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

PRIOR to the reading of the paper for the evening, Dr. GURDON BUCK presented a patient upon whom he had performed the operation of

EXSECTION OF THE HEAD OF THE HUMERUS.

The chief particulars of the case were as follows:—Eighteen months ago the man stumbled over a dog, and fell with great force upon his right shoulder. Soon after, he began to feel some pricking pains about the joint, and motion was somewhat impaired. Rest gave partial relief. Some months after, the operation of *brisement force* was performed upon the shoulder in St. George's Hospital, London, and for a time the man thought he was benefited by it. In April last an opening formed and discharged matter, and continued to discharge up to the time of the operation. The probe did not readily encounter dead bone; but the whole history of the case pointed to a diseased condition of the bone; and the lack of benefit by treatment indicated that the only resource was to excise the head of the humerus.

An instrument was exhibited which was employed for carrying the chain-saw around the bone. It is an apparatus similar to Bellocque's sound, traversed by a watch-spring, which has an eye for the insertion of a ligature, to which the chain-saw can be attached. The mode of dressing was worthy of notice. The wound was first lightly stuffed with lint wet in a carbolized solution, after which it was covered with sheet-lint wet in collodion, which formed for the wound an artificial scab. Such an appliance will remain for eight or ten days, but very little swelling will take place, and it saves the disturbance of a daily dressing. The process of suppuration seems to be retarded under this dressing, although the process of granulation will go on.

Raising the arm from the body was the chief motion now impaired, but that was improving. The patient thinks he can lift as much with this arm as with the other.

DR. PURPLE took the chair, and DR. FLINT proceeded to the reading of the following paper for the evening:

“UPON THE RESEARCHES OF CURRY, AND THE RECENT VIEWS WITH REGARD TO THE REMEDIAL USE OF WATER.”

The researches of Curry were made at the close of the last and the beginning of the present century.

It appeared, from the reading of the paper, that Curry resorted to the use of water extensively in the treatment of a great variety of diseases. Not only were his observations made with regard to the effect of cold, but also of warm water. The results of his experience were extensively quoted, and the conclusion was easily drawn, that the water-treatment of to-day is essentially a revival of a practice adopted three-fourths of a century ago. It was an interesting fact also that Curry appreciated and clearly set forth the importance of the thermometer, and indeed the present axillary and self-registering thermometer were anticipated by him. The quotations from Curry, although so old, sounded like the fresh observations of a master-mind upon this subject, so fully were they in keeping with the most recent views concerning the value of this remedial agent.

THE COLD PACK.

Prof. Flint's method of using the cold pack is as follows:

Wrap the body in a sheet wet in cold water, and then sprinkle with a watering-pot, and continue the pack from ten minutes to half an hour, according to the temperature and condition of the pulse. Used in this manner he is of the opinion that we obtain all the benefits of the *bath*.

Special reference was made to the internal use of water in the treatment of disease. The quantity to be taken in the treatment of fever should be regulated by the feelings of the patient. Air, food, and drink; these form the tripod whence emanate the laws which should govern the hygienic management of our cases of fever. The internal use of water was suggested in the treatment of renal affections. A case was related in which the urine was scanty, albuminous, and of very low specific gravity, accompanied by other symptoms of grave character, but was brought to a successful termination by water-treatment, originated and executed by Dr. Perry, formerly house-physician at Bellevue Hospital. The chief feature of the treatment was the administration of four ounces of water, or milk and water, every half hour, regularly and steadily persisted in.

DR. LEALE presented the records of several cases in which he had resorted to the use of water with good results.

Correspondence.

TREATMENT OF FRACTURE OF CLAVICLE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Fracture of the clavicle is of so frequent occurrence, and has been so annoying to the surgeon, that any evidence bearing upon its successful, and withal simple treatment, may be of service.

The form of dressing, in my opinion, superior to all others in simplicity, ease to patient and surgeon, and efficiency of results, is Professor Sayre's adhesive-plaster plan, modified and applied as follows:

Three straps are employed.

The first encircles the arm of the injured side close to the borders of the axilla, and is then carried over the lower angle of the scapula and around the body tight enough to hold the shoulder well back.

The second piece commences over the point of the sound shoulder, and is carried obliquely across the back and over the olecranon of the injured side, drawing the elbow forward and close to the side, and then extending obliquely across the chest front to the place of commencement.

The third strap commences over the pectoral muscle, and is carried snugly over the point of the shoulder of the injured side, and obliquely down the back.

This third strap can be made a material aid in antagonizing the unfavorable action of the sterno-cleido-mastoid, subclavius, pectoralis minor, and deltoid muscles, while the support the shoulder derives from its influence in fixing the scapula and otherwise, materially contributes to the comfort of the patient and the favorable result.

To prevent pain and embarrassment of the circulation in the arm by the first strap, I employ a splint extending from near the point of the shoulder well down over the biceps muscle. This splint should be solid, hollowed to fit the arm, and just wide enough to

prevent the strap from compressing the arm too much laterally.

The strap around the splint and arm should be stitched together to prevent slipping, and be loose enough to leave the arm a little free posteriorly.

The straps are cut three, or three and a half inches in width, and should be stitched together if one continuous strap cannot conveniently be obtained long enough to encompass the body.

The forearm, suspended in a sling, can be raised or lowered at will, if the elbow becomes painful.

When properly applied, this plan forms a dressing for this frequent injury which will insure comfort to the patient and recovery without deformity.

CHAS. E. SLOCUM, M.D.

DEFIANCE, OHIO.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from December 19, 1874, to January 2, 1875.

COOPER, GEO. E., Surgeon.—Relieved from duty at Benicia Barracks, and assigned to duty at Point San José, Cal. S. O. 124, Department of California, Dec. 11, 1874.

BENTLEY, E., Assistant Surgeon.—When relieved by Surgeon Cooper, to report to the Medical Director at these Headquarters for duty. S. O. 124, c. s., Dept. of California.

PAULDING, H. O., Assistant Surgeon.—Assigned to temporary duty at Fort Snelling, Minn. S. O. 275, Dept. of Dakota, Dec. 14, 1874.

WHITE, R. H., Assistant Surgeon.—Granted leave of absence for one month. S. O. 208, Dept. of the Gulf, Dec. 16, 1874.

WINNE, C. K., Assistant Surgeon.—Assigned to duty at Sidney Barracks, Nebr. S. O. 185, Dept. of the Platte, Dec. 17, 1874.

JACKSON, D., Assistant Surgeon.—Assigned to temporary duty at these Headquarters. S. O. 199, Dept. of Texas, Dec. 21, 1874.

SEMIG, B. G., Assistant Surgeon.—Assigned to duty at Camp Halleck, Nevada. S. O. 124, c. s., Dept. of California.

SKINNER, J. O., Assistant Surgeon.—Relieved from duty at the Presidio, and to comply, without delay, with par. 3, S. O. 260, A. G. O., Nov. 30, 1874. S. O. 159, Dept. of California, Dec. 22, 1874.

ABADIE, E. H., Surgeon.—Died at St. Louis, Mo., Dec. 22, 1874.

THE ACADEMY OF MEDICINE OF PARIS.—This important body is on the eve of undergoing radical changes, time having rendered its organization somewhat cumbersome. Founded in 1820, the Academy, up to 1835, had to bear different modifications, and is now divided into eleven sections. These comprise medicine proper, surgery, obstetrics, and allied sciences, making altogether one hundred members. A committee lately appointed has reported, by the organ of M. Chauffard, that a complete change is necessary, and propose to diminish the number of sections, give them new names, and reduce the total of the members from one hundred to sixty. The discussion will be carried on privately, and it is expected that a good deal of opposition to this scheme will be started. It is agreed on all hands that M. Chauffard's report is a masterpiece as regards diction, lucidity, reasoning, and skilful appreciation of the part which the Academy should take in the progress of science.

Medical Items and News.

THE BELLEVUE MEDICAL BOARD.—The Commissioners of Charities and Correction met December 5th, to hear arguments in regard to the reinstatement of those physicians who had been members of the old Medical Board of Bellevue Hospital and who had been removed by the preceding Commissioners of Charities and Correction. Austin Flint, Jr., M.D., appeared for the old Medical Board, and William A. Hammond, M.D.; John C. Dalton, M.D.; Henry B. Sands, M.D.; Thomas M. Markoe, M.D.; Drs. Loomis, Krackowizer, and Polk, for the present Medical Board.

Dr. Flint took the ground that those members of the old Board who had not been reappointed had served the city for a long term of years faithfully and honorably. This long term of service had not been considered, but these gentlemen had been removed without any reason, and treated outrageously. Their services demanded the consideration of the Commissioners, and they should be reinstated as members of the present Medical Board, and permitted to continue their valuable services to the city. Those who represented the present Medical Board argued, on the other hand, that no invidious distinctions had been made, but the entire old board had been dismissed. Eight medical gentlemen had been selected, representing the different medical schools and the profession at large, and they had selected the rest of the new Medical Board. While this has been a great advantage to the other schools which contribute to the support of Bellevue Hospital, it has not injured the Bellevue Medical College. More than twice as many students of medicine, it was claimed, have been drawn to the city this winter by the superior advantages offered them, and the cause of medical education has been served by the change.

The Commissioners heard the arguments and reserved their decision. Dr. Flint expected to be supported by Dr. James R. Wood, Dr. Van Buren, and others, but for some reason they were not present. The resignation of Commissioner Donnelly will postpone the decision until another Commissioner is appointed.

DIPHTHERIA.—The following report of the Sanitary Committee of the Board of Health of this City upon Diphtheria is approved and published by the Board:

Mode of Attack.—Diphtheria is caused by the inoculation of the air-passages with the diphtheritic poison, which from this point infects the whole system; the local inflammation is attended by the formation of membrane (exudation); the fever and general symptoms are the result of this local infection.

How it Spreads.—Diphtheria is therefore a contagious disease (not perhaps as marked as scarlet fever), induced by contact with persons and objects infected. It may be diffused by the exhalations of the sick, by the air surrounding them, or directly by the exudation, communicated in the act of kissing, coughing, spitting, sneezing, or by the infected articles used, as towels, napkins, handkerchiefs, etc. The poison clings with great tenacity to certain places, rooms, and houses, where it may occasion cases after the lapse of months.

Symptoms.—In ordinary attacks the poison begins to act the moment it lodges upon the tissues, but, like a vaccination, causes but slight sensible effects in from two to five days; then there is marked prostration, dryness of throat, and pricking pain in swallowing; the throat becomes red, and patches of white exuda-

tion appear, and the glands of the neck swell. In mild cases these symptoms subside on the third or fourth day from their appearances; if more severe, these symptoms may be prolonged; if unfavorable, the fever increases, the local inflammation spreads, and exhaustion rapidly follows.

Predisposing Conditions—the Person.—Diphtheria attacks by preference children between the ages of one and ten years (the greatest mortality being in the second, third, and fourth year); children of feeble constitution, and those weakened by previous sickness; and those suffering from catarrh, croup, and other forms of throat affections.

Social Relations.—All classes are liable to diphtheria where it is prevailing, but those suffer most who live on low, wet grounds; in houses with imperfect drains or surrounded by offensive matters, as privies, decaying animal and vegetable refuse; in damp rooms, as cellars; in overcrowded and unventilated apartments.

Seasons.—Diphtheria is not affected by either heat or cold, drought or rain.

Precautions—(a.) The Dwelling or Apartment.—Cleanliness in and around the dwelling, and pure air in living and sleeping rooms, are of the utmost importance where any contagious disease is prevailing, as cleanliness tends both to prevent and mitigate it. Every kind and source of filth around and in the house should be thoroughly removed; cellars and foul areas should be cleaned and disinfected; drains should be put in perfect repair; dirty walls and ceilings should be lime-washed, and every occupied room should be thoroughly ventilated. Apartments which have been occupied by persons sick with diphtheria should be cleansed with disinfectants; ceilings lime-washed, and woodwork painted; the carpets, bed-clothing, upholstered furniture, etc., exposed many days to fresh air and the sunlight (all articles which may be boiled or subjected to high degrees of heat should be thus disinfected); such rooms should be exposed to currents of fresh air for at least one week before re-occupation.

(b.) When Diphtheria is Prevailing.—No child should be allowed to kiss strange children nor those suffering from sore throat (the disgusting custom of compelling children to kiss every visitor is a well-contrived method of propagating other grave diseases than diphtheria); nor should it sleep with nor be confined to rooms occupied by, or use articles, as toys, taken in the mouth, handkerchiefs, etc., belonging to children having sore throat, croup, or catarrh. If the weather is cold the child should be warmly clad with flannels.

(c.) When Diphtheria is in the House or in the Family.—The well children should be scrupulously kept apart from the sick in dry, well-aired rooms, and every possible source of infection through the air, by personal contact with the sick, and by articles used about them or in their rooms, should be rigidly guarded. Every attack of sore throat, cough, and catarrh should be at once attended to; the feeble should have invigorating food and treatment.

(d.) Sick Children.—The sick should be rigidly isolated in well-aired (the air being entirely changed at least hourly), sunlit rooms, the outflow of air being, as far as possible, through the external windows by depressing the upper and elevating the lower sash, or a chimney heated by a fire in an open fireplace; all discharges from the mouth and nose should be received into vessels containing disinfectants, as solutions of carbolic acid, or sulphate of zinc; or upon cloths which are immediately burned; or if not burn-

ed, thoroughly boiled, or placed under a disinfecting fluid.

By order of the Board,
CHARLES F. CHANTLEY,
President.

EMMONS CLARKE, Secretary.

A circular nearly similar to the above in its general features has likewise been issued by the Board of Health of the City of Brooklyn.

A NEW EDITION OF THE ENCYCLOPÆDIA BRITANNICA is announced by the publishers, Messrs. A. & C. Black, of Edinburgh, to be edited by Mr. T. S. Baylis, Professor of Rhetoric and Metaphysics in the University of St. Andrews. The ninth edition is not to be merely an alteration and adaptation of the eighth, but a reconstruction, in which the new matter will amount to considerably more than half the whole. Among the contributors are Prof. Whitney, of Yale College; Dr. W. B. Carpenter, one of the leading writers for the past twenty years and more on Physiology; Prof. Max Müller, who will discuss the Aryan races and languages; Dr. E. B. Taylor, the author of Primitive Culture, who writes on Anthropology. Prof. Huxley contributes articles on the Animal Kingdom and Amphibia; St. George Mivart, on Apes; Alfred R. Wallace, on Acclimatization; and Dr. Lethby, on Adulteration.

The ninth edition will, like the eighth, fill twenty-one quarto volumes of 800 to 900 pages each. The type of the specimen sheets is very clear, and illustrations of varied character abound. Three volumes a year are to be issued, beginning in January, 1875, at 30 shillings each (\$7.50).

A PATENT DECISION AFFECTING DENTISTRY.—For several years past the dockets of all the United States Circuit Courts have been crowded with suits brought by the Goodyear Dental Vulcanite Company against dentists, for infringing the Cummings patent, covering the hard rubber plates used for inserting artificial teeth. Between 2,900 and 3,000 suits have been brought against infringers of this patent.

In the hope of ending the threatened prolonged litigation, a full bench of the United States Circuit Court—three judges sitting—met in the Eastern District of Michigan, at Detroit, and arguments on both sides was heard on Nov. 5, 6, and 7 last, on a test case selected to determine the rights of the patentee. The complaint was against one George Willis. Judge Emmons, in behalf of the Court, has just rendered an opinion fully sustaining the validity of the patent. After alluding to "the exceptional feeling and excitement existing in the minds of the numerous defendants in suits brought on this patent," and discussing the questions of law involved, he suggested to the numerous other defendants having like cases pending, the uselessness of additional argument before the Circuit Courts.

EXTIRPATION OF A FIBRO-CYSTIC TUMOR OF THE UTERUS WITH THE LATTER AND ITS APPENDAGES.—In the *Canada Medical Record* of November, Professor Trenholme, of Montreal, reports a case of a woman, aged thirty-three years, from whom he had removed, by abdominal section, a tumor which, together with its appendages, weighed sixteen pounds. On the thirty-fifth day the patient was able to walk out of the house.

IN A DUEL recently fought near Grand Bay, Mississippi, by two residents of Mobile, Dr. Benjamin D. Lay, of Mobile, actuary of the Grangers' Life and Health Insurance Co., shot and killed Mr. A. H. Tardy, agent in a rival company.

NARCOTIZING HORSES.—The *Gaz. Méd. de Bordeaux* says that an eminent veterinary surgeon has informed the Medical and Surgical Society of that City, that the coachmen of certain families had been for some time in the habit of administering chloral to the horses in their charge, so as to make them easier to ride or drive. It appears that the drug acted like a charm, for horses which had previously been so spirited as to give much trouble to their driver, became as quiet as lambs after a few days of this hyposthenic treatment. The change naturally attracted the attention of the owners of the animals, and they sent for the veterinary surgeon to ascertain the cause of the sudden gentleness. That functionary noticed a certain tendency to sleep in the animals; but scarcely knew to what to refer this unusual condition, when, in one of his visits, he chanced to find a bottle half full of chloral. When the coachman was questioned regarding the use he made of the drug, he confessed, after much hesitation, that, following the advice of a brother "whip," he gave the horses a dose of chloral every morning to make them go quietly, and further, that many of the fraternity in Bordeaux followed the same plan.

SYRACUSE UNIVERSITY.—A citizen of Syracuse, whose name has not been made public, has presented the University in that city with \$20,000. The same gentleman will also endow a professorship in the University at some future time, when his name will be announced. Since last June the University has received contributions amounting to \$175,000, which brings up the endowment of the institution to \$800,000.

CREMATION.—A California paper suggests some readings on plates of funeral urns in the future: "Charles Pupker, 3½ lb., cremated July 9th, 1879. For wife of above, see third pickle-bottle on next shelf; little Tommy, burnt up Sept. 16th, 1881. Jane Matilda Perkins, Oct. 3d, 1883, put up by the Alden Corpse Cremating Company. None genuine without signatures."

VIVISECTION.—An attempt has been made in the English courts to enforce the law for the prevention of cruelty to animals against the operators of vivisections made in the interest of science. *The New York Herald*, in a recent issue, says:—"Any thoughtful person not blinded by fanatical zeal, can comprehend that the delegation of authority to prevent this cruelty, wherever made, is made always to suppress the flagrant exhibitions of brutal impulses that are horrifying to ordinary sensibilities, and that lawmakers never intended to embarrass the legitimate pursuits of science by this sort of law; least of all could they ever have intended to prevent the sacrifice of a few of the lower animals in the interests of humanity generally. But the English society has the same blind bigotry on this point that has been manifested by our own society, and takes the same morbid view of the relations of man to the brute creation. It endeavored to punish a vivisection made in the presence of a learned society, and its complaint was dismissed. If this act cannot be punished in England it cannot here, where there is far less professional philanthropy, and we hope the society will take note of the decision on the other side."

DR. E. WARREN SAWYER, a graduate of the Harvard Medical School, has obtained the position of Lecturer on Obstetrics at the Rush Medical College, Chicago, after a competitive examination with thirteen others. Each candidate was called on to deliver an extemporaneous lecture on a given subject before the Faculty and students.

A TRAINING SCHOOL FOR NURSES has been established at Montreal. Its foundation is due mainly to the liberality and labor of Miss Mousy, a young lady who was trained by the Countess Gasparin, in whose honor the institution has been named "The Gasparin Training School and Nurse House." The plan of management, as given by the *Canada Medical Journal*, is as follows: Each nurse binds herself to serve three years, the first six months free, and after that to receive ten dollars per month, and two suits of uniform annually, and comfortable board and lodgings at the "Home" when unemployed. Miss Mousy has contributed the property from her private purse, and also renders her services free. The expenses have been met by private subscription, and the concern is now nearly self-supporting. It contains about 40 beds.

A PRIZE FOR AN ORIGINAL ESSAY on the use of electricity in acute diseases is offered by Dr. Geo. M. Beard, editor of the *Archives of Electrology and Neurology*. The essay must be founded entirely on the original experience of the author, and should not exceed fifteen pages of the above-mentioned journal, in which the successful paper is to be published in November next. The essays should be handed in by Sept. 1, 1875. The amount of the prize is twenty-five dollars.

THE TROUBLE IN THE PARIS SCHOOL OF MEDICINE.—The Medical School of Paris was partially reopened after the late disturbances, on December 1st. Two of the apparitors belonging to the school had orders to allow only fourth-year students to enter the room where M. Chauffard was to resume his interrupted course of lectures, and he commenced with an audience of thirty-nine. But after the lapse of a few minutes, the students departed one by one, until, according to the *Progrès Médical*, M. Chauffard had only three left to listen to his, doubtless, carefully prepared discourse.

THE WARREN TRIENNIAL PRIZE.—The Trustees of the Massachusetts General Hospital give notice that the next Warren Prize, amounting to somewhat less than \$400, will be awarded to the author of the best essay, considered worthy of a prize, on any subject in physiology, surgery, or pathological anatomy, embodying original researches.

Each essay should be accompanied with a sealed envelope containing the author's name and address, and be sent to the Resident Physician of the Massachusetts General Hospital before February 1, 1877.

AN ADJOURNED MEETING OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK will be held Tuesday evening, Jan. 12th, when Dr. George M. Beard will read a paper entitled, "The Relations of the Medical Profession to the Delusions of Spiritualism, Animal Magnetism, Mind Reading, etc. How these should be detected and exposed."

MR. HEATH'S solution, referred to by Dr. Sell in our last number, has the strength of a scruple of nitrate of silver to the drachm, and is introduced through a hard rubber urethral syringe by means of a mop.

THE AMERICAN JOURNAL OF OBSTETRICS.—Our attention has been called to the fact that no mention was made of this journal when referring to the different periodicals published in this city. We are at a loss to account for this omission, and merely say that it was by the merest accident.

DR. HENRY G. PIFFARD, of this city, has been appointed Honorary Dermatologist to the Board of Health.

ERRATUM.—In Prof. Clark's article, vol. 10, No. 1, page 2, second column, 31st line from the bottom, for *central* read *cerebral*.

Original Lecture.

CARDIAC DILATATION.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF PRACTICAL MEDICINE AND PATHOLOGY IN THE MEDICAL DEPARTMENT OF NEW YORK UNIVERSITY.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—To-day I will invite your attention to the subject of cardiac dilatation, which in its causation and anatomical changes is closely allied to cardiac hypertrophy, the subject of our last lecture.

By the term *cardiac dilatation*, you may understand a condition of the heart in which there is an increase in the capacity of its cavities; but the contractile power of the organ is diminished.

There are three recognized forms or stages of *cardiac dilatation*.

First:—*Simple cardiac dilatation*, in which the capacity of the heart cavities is increased without any marked change in the cardiac walls. Such a condition is apt to occur in connection with convalescence from any disease in which there has been great impairment of nutrition, such as typhoid fever, etc.

Second:—*Hypertrophous cardiac dilatation*.—In this form there is increase in the heart-cavities, accompanied by a slight increase in the thickness of the heart walls; but the contractile power of the heart is diminished. This condition may occur as the result of a degeneration of eccentric hypertrophy, or it may occur independent of any hypertrophy of the cardiac walls.

Third:—*Atrophic cardiac dilatation*.—In this form the capacity of the heart cavities is markedly increased, and the cardiac walls are markedly thinner than normal. Sometimes the ventricular walls diminish to not more than two or three lines in thickness, and the auricular walls may become so thinned that they will present the appearance of a simple membrane. Under these circumstances the contractile power of the heart is almost lost. Anatomically as well as clinically the significance of cardiac dilatation is in proportion to the excess of the capacity of the cavities over the thickness of the cardiac walls. A cardiac cavity may be very much increased in capacity, but so long as there is a corresponding increase in the muscular power of its walls sufficient to meet the demand of the increased work they are called upon to perform, there will be little or no disturbance to the general circulation. Eccentric hypertrophy and hypertrophous dilatation approach each other very closely, and it is often very difficult to draw the line of separation between them.

Morbid Anatomy.—One or all of the heart cavities may be the seat of dilatation. The shape of a heart when it has undergone dilatation is changed according to the cavity which is the seat of the dilatation. If the dilatation is confined to the right ventricle, the heart will be increased in breadth; while if the dilatation affects mainly or only the left ventricle, the heart will be increased in length. Ordinarily when one cavity is dilated the remaining cavities are more or less affected in the same manner.

Cardiac dilatation occurs most frequently in the auricles; next in the right ventricle; and last of all in the left ventricle. While the left ventricle is less liable than the right to become the seat of dilatation, it is more liable to become the seat of hypertrophy. When all the cavities are dilated, the entire organ is in-

creased in size, and assumes rather an ovoid shape. When the ventricles are excessively dilated, the trabecule are sometimes reduced to the condition of fleshy tendinous cords. When the walls of the left ventricle are very much thinned, they collapse when the ventricle is opened. The anatomical changes which take place in the muscular tissue of the dilated cardiac walls vary with the degenerative process which precedes and attends the dilatation. When it results from pericarditis or myocarditis, there is serous infiltration and granular degeneration of the muscular fibres. When it is the result of fatty metamorphosis the muscular fibres undergo fatty degeneration, the process of which will be described under the head of fatty heart.

In hypertrophous dilatation, it is often impossible, even by microscopic examination, to determine the exact changes which the muscular fibres undergo; the abnormal state of the muscular fibres can only be determined by the other evidences of feeble heart power. You must be careful not to mistake a heart distended with blood and relaxed by putrefaction for a dilated heart. The distinctive marks of a heart softened by the putrefactive process are its extreme softness, its saturation with the coloring matter of the blood, and the evidences of decomposition in other parts of the body. Closely connected with the morbid anatomy of cardiac dilatation, is its causation.

Etiology. The causes of cardiac dilatation vary very widely. One class of causes may be included under the head of the immediate changes which take place in the muscular tissue of the walls of a heart that has undergone dilatation. I have already alluded to these. First, we have the changes in the muscular tissues which accompanies pericarditis and endocarditis; second, fatty degeneration of the muscular fibres; third, a cardiac dilatation which occurs with certain forms of protracted disease, such as typhoid fever, where the most careful microscopical examination will fail to detect any uniform change in the muscular fibre, except, perhaps, a general atrophy of all the tissues. One or all of these tissue changes may be regarded as causes of cardiac dilatation; again all the causes of cardiac hypertrophy may become the causes of dilatation in a heart which has a feeble resistant power. This group of causes may be classed under three heads:—*First*: *internal pressure during a cardiac diastole*. The wall of a heart may become weakened by the changes which occur in certain prolonged diseases, or it may become the seat of serous infiltration or fatty degeneration; then an abnormal pressure within its cavities during its diastole will cause the cardiac walls to yield beyond their normal limits. Such distension is certain to be followed by permanent dilatation of its cavities. Most of the valvular lesions which have recently occupied our attention may be the direct cause of such internal pressure during the cardiac diastole, after the manner I have already described in connection with the etiology of cardiac hypertrophy. Generally (as I have endeavored to show you), when the cardiac cavities become distended beyond their normal limit, and thus temporarily lose their contractile power, rapid hypertrophy of the cardiac walls is developed, which compensates, and to a certain extent overcomes the dilatation. But if the cardiac walls are enfeebled by any of the degenerative changes to which I have referred, such compensating hypertrophy does not take place, and any valvular lesion which will permit a double current of blood to flow into a cardiac cavity during its diastole, the heart walls having become enfeebled by degenerative changes, will give rise to cardiac dilatation. *Second*: when the muscular tissue of the heart

is the seat of primary fatty degeneration, after a time dilatation of the cavities takes place, the normal blood pressure being sufficient to produce it. In the same manner will a heart become dilated when its walls are the seat of myocarditis. That form of cardiac dilatation which follows typhus and typhoid fever or chlorosis, usually disappears when the attenuated muscular fibres of the heart, with the rest of the muscles, regain their normal condition; but the dilatation which results from fatty degeneration of the muscular walls of the heart steadily increases. *Third*: there is still another cause of cardiac dilatation which has already been referred to in connection with the history of valvular diseases; that in degeneration of the muscular substance of the heart which is the seat of eccentric hypertrophy. The manner of its development I have already described. The dilatation does not occur in this class of cases until long after the development of the valvular diseases which give rise to the hypertrophy. Usually the hypertrophy becomes very extensive before the degenerative dilatation commences; but when it once begins, it progresses very rapidly, and the failure of heart power is attended by very distressing symptoms. The power that obstruction to the pulmonary circulation has in producing dilatation of the right ventricle has been considered in connection with valvular diseases of the heart. When these obstructions exist, eccentric hypertrophy rather than dilatation is generally developed.

Symptoms. The symptoms that attend the development of cardiac dilatation chiefly depend upon the character and seat of the dilatation. In simple cardiac dilatation, the heart walls possess normal power, but the capacity of the cavities is increased, and the amount of blood to be expelled with each cardiac pulsation is greater than normal, consequently there is labored action of the heart (often to such an extent that it may readily be mistaken for the action of a hypertrophied heart), yet the force of the heart's action does not increase, and therefore we have a feebleness of the radial pulse. The rhythm of the heart's action will not be disturbed. In that form termed atrophic dilatation, you have a very different state of affairs. The heart cavities are not only dilated, but the walls of the cavities are thinner than normal,—the heart power is insufficient for the expulsion of the blood from its cavities, and as a result, there is a labored action, a markedly feeble radial pulse, and the heart, on account of the increased amount of labor, staggers with action, the arteries are improperly filled with blood, the veins become over distended, the rhythm of the heart's action is disturbed, and the radial pulse becomes weak and intermittent. These latter are points of special importance, as affecting the question of prognosis; for, if a patient has all the symptoms of cardiac dilatation without an irregular and intermittent pulse, the prognosis is comparatively good. The same disturbance of the circulation occurs in that form of dilatation which is developed from the degeneration of eccentric hypertrophy.

The first, and perhaps the most constant symptom, which is common to all varieties of cardiac dilatation is cardiac palpitation. At times this palpitation is very severe and distressing. There is almost constantly a sense of painful palpitation in the region of the heart. Very soon after the palpitation has manifested itself, the patient will begin to suffer from dyspnoea on slight exertion; when he is quiet he suffers very little. As the irregularity of the heart's action and the palpitation increases, the patient's countenance assumes a pale, languid, anxious expression, with more or less lividity of the lips. On excitement

or active physical exertion, the entire face and neck become livid; the pulse, which usually is regular, for a time becomes irregular and intermittent. In this condition patients often live some time in comparative comfort, but they are conscious, not only of a loss of physical, but of mental power, and are troubled with dyspeptic symptoms, and a sense of fullness about the epigastrium. As the disease advances, and the cardiac dilatation reaches a point at which it is always troublesome, the patient has constant dyspnoea, which becomes severe on slight exertion; cardiac palpitation is always present, and often accompanied by attacks of syncope. The countenance now assumes a still more anxious expression, the lips retain a constant lividity, and the pulse is still more irregular and intermittent. With these symptoms there will be scantiness of urine, and it will very likely contain albumen. The feet and ankles become œdematous, the œdema gradually extend upwards, until the patient is in a state of general anasarca. The respiration now becomes very difficult, so much so that the patient cannot lie down, but is obliged to sit with his head inclined forward and resting upon some firm support, and he is usually unable to utter more than a single word at a time. The extremities become cold and blue; the mind wanders, and the patient dies from general anasarca with pulmonary œdema. In nearly all cases of cardiac dilatation, when it becomes extensive, the surface of the body will have a yellow tinge, showing that the circulation through the liver is more or less disturbed.

During the latter stages of this affection, most violent paroxysms of dyspnoea will occur, and it will seem as though the patient must die in some of them, yet they rarely prove fatal; but the patient passes into a state of coma and dies unconscious. In extensive cardiac dilatation there is always danger from sudden syncope, which may prove immediately fatal. To describe to you *all* the phenomena that attend the different degrees of cardiac dilatation, modified as they are by the idiosyncrasies of the individual, as well as by the varying extent of the valvular changes which may be present, would be almost an endless task.

* The phenomena already described, which are present to a certain extent in all cases, are sufficient to lead to at least a problematical diagnosis. Besides, the physical signs of this affection, if properly appreciated, are very distinctive and generally will remove all doubts in connection with a case. You must be prepared, however, to find that the symptoms which develop in different cases greatly vary; but the variation depends more upon the valvular lesions which are developed in the course of the dilatation than upon the dilatation itself.

Physical Signs.—Upon inspection it will be noticed that the visible area of the apex beat is increased; but it is so indistinct that it will be difficult to determine by inspection the exact point where the apex strikes the walls of the chest. This is especially the case if the chest walls are covered with much adipose tissue or are at all œdematous.

In persons with thin chest walls you will sometimes notice an undulating motion over the whole of the precordial space. The precordial region is never prominent as is sometimes seen in eccentric hypertrophy.

Upon palpation you will readily distinguish dilatation from hypertrophy by the feebleness of the cardiac impulse. Although it can sometimes be felt as far to the left as is the axillary line, yet there is an absence of the lifting, forcible impulse which attends cardiac hypertrophy. It is often difficult to determine the exact point of its maximum intensity, but it will be noticed that over the entire precordial space there is an

undulating motion, and the apex beat will be diffused, wanting in force, and resembling a feeble step. Sometimes with this character of apex beat a purring thrill will be present. I stated to you that a purring thrill with the apex beat was almost characteristic of mitral stenosis; but you may have a purring thrill with mitral regurgitation, when the regurgitation is associated with cardiac dilatation.

Percussion gives a greatly increased area of lateral dulness. The area will be increased to the right of the right side if the heart is the seat of the dilatation, and in some cases the increase will extend an inch or more to the right of the sternum. If the left side of the heart is the seat of the dilatation, the area of dulness will be increased to the left, and may extend well into the axillary space.

The shape of the increased precordial area will be oval. This point is of importance in the differential diagnoses between cardiac dilatation and pericardial effusion. The area of the superficial cardiac dulness is not increased in the same proportion as the deep-seated, as is the case in cardiac hypertrophy. Dilated auricles are recognized by an upward increase in the area of dulness. When the jugular veins are permanently dilated and knotted, the existence of dilatation of the right auricle will not be difficult to determine.

Auscultation.—The sounds of a dilated heart are short, abrupt, and feeble. The second sound is often inaudible at the apex, and the two sounds are of very nearly equal duration. Whenever a cardiac murmur has existed prior to the development of the dilatation, as the dilatation develops the rhythm of the murmur is lost, and it becomes simply a confused murmuring sound. This condition has been denominated *asystolia*. It is a condition in which you are unable to determine whether the murmur is synchronous with the first or second of the heart; and pauses or intermissions occur at irregular intervals, which are of more frequent occurrence during exercise than when the patient is quiet. When the asystolic condition is present, prognosis is very unfavorable, independent of the general condition of the patient; for it shows that, in addition to the valvular lesions which may be present, cardiac dilatation has been developed to such an extent as to give rise to complete confusion of the normal heart sounds. Under such conditions the patient is liable to die at any moment. *Asystolism* is generally accompanied by a diffused cardiac impulse, which is peculiar, and is readily appreciated by the ear as it rests over the precordial space. The respiratory murmur is diminished in intensity over the whole of the upper portion of the left lung.

Differential Diagnosis.—The diagnosis of cardiac dilatation rests mainly on the following conditions: Feeble action, undulating impulse, indistinctness of apex beat; lateral increase in the area of percussion dulness (very nearly square in its outline); short, abrupt, and feeble heart sounds; feeble, irregular, and intermittent pulse, accompanied by the general symptoms of systemic and pulmonary obstruction and congestion.

The differential diagnosis between cardiac hypertrophy and cardiac dilatation is never very difficult. The symptoms of the two conditions differ very materially. For instance, the heart sounds are intensified in hypertrophy and feeble in dilatation. In both cases there is an increased area of apex beat; but in hypertrophy it is full, distinct, and forcible; while in dilatation it is feeble, diffused, and indistinct. An individual with cardiac hypertrophy apparently has a more than normally vigorous and forcible action of the heart, which is increased by active exercise, and has

none of the feebleness of heart action which attends the person with cardiac dilatation. The fact that an individual has had cardiac hypertrophy with all its attendant symptoms, but now has a tired expression of countenance, livid lips, and daily decrease of physical vigor, accompanied, it may be, by œdema of the feet, shows that cardiac hypertrophy has become cardiac dilatation. Dilatation of the right side of the heart, in addition to the signs already detailed, is to be recognized by changes produced in the veins. The presence of distended, irregular, turgid jugular veins, tells very positively of dilatation of the right auricle; and pulsation in the jugulars, accompanied by feeble heart action and increase in the area of cardiac dulness upon the right, speaks very distinctly of dilatation of the right ventricle associated with tricuspid regurgitation. It is sometimes somewhat difficult to make a differential diagnosis between pericarditis with effusion and cardiac dilatation. In pericarditis with effusion the area of dulness is increased, and there is a feeble apex beat, and sometimes an undulating impulse, all of which are present in cardiac dilatation. The heart sounds, however, in pericarditis are more removed from the surface than they are in dilatation, and the area of percussion dulness is pyriform, while in dilatation it assumes nearly a square shape. Besides these distinguishing features, you will rarely meet with a case of pericarditis, even with effusion, when you may not hear a friction sound at some point; but in cardiac dilatation there is an entire absence of friction sound, no matter in what position the patient may be placed. In addition to these differences in the physical signs, the history of the case and the accompanying rational symptoms will be of great assistance in solving the question of differential diagnosis between either cardiac dilatation and pericarditis or cardiac hypertrophy and fluid in the pericardium. The differential diagnosis between enlargement of the heart, either from dilatation of its cavities or hypertrophy of its walls and thoracic tumors, will sometimes present itself. Both of these cardiac conditions may be developed as the result of, or in connection with, thoracic aneurisms. One very reliable differential sign is the direction of the increased area of percussion dulness in thoracic aneurisms and mediastinal tumors, for they always enlarge upward and to the right or left; while in cardiac enlargement the area of dulness is increased in a lateral direction and downward. This fact, taken in connection with the other physical and rational signs of aneurism, is generally sufficient for the differential diagnosis between these conditions.

Consolidation of lung tissue in the region of the heart may give rise to some of the signs of cardiac enlargement, but the other attending physical signs of pulmonary consolidation will enable you to distinguish between the dulness on percussion produced by the pulmonary consolidation and the increased area of dulness produced by the cardiac enlargement.

Prognosis.—The prognosis in cardiac dilatation is always bad, and the danger to life is increased in proportion to the excess of the capacity of the cavities over the thickness of their walls. The more the capacity of the cavities is increased, the greater the thinning of the cardiac walls, and the greater the danger to life. Feebleness of the general muscular system and impoverishment of the blood greatly increase the danger. If these patients have been subject to paroxysms of dyspnea and attacks of syncope, the prognosis is especially bad, for then there is constant danger of sudden death. The dangers attending any intercurrent pulmonary disease are always great.

Whenever dropsy of any kind has been developed,

prognosis is very bad. When this condition is developed, few patients, even with the best of care, live more than eighteen months; the majority die within one year. In those cases in which the pulse is regular, or only becomes irregular after violent physical exertion, the prognosis is comparatively good, for much can be done to relieve and prolong the life of such patients. When general anasarca has been developed, and the patient is no longer able to assume the recumbent posture, you will be able to give temporary relief, but it will be only temporary. This brings us to the question of treatment.

Treatment.—As regards complete recovery, the treatment of cardiac dilatation is altogether unsuccessful. It is not a curable disease. Even the good effects of palliative measures are only temporary. There are, however, two important objects to be aimed at in the management of a case of cardiac dilatation.

First, Maintenance of the general nutrition at the highest possible point, as the most certain means of preventing flaccidity of the cardiac walls; *second*, prevention, as far as possible, of all irregular or violent action of the heart. To obtain the first object, the diet must be of the most nutritious character, should be taken in small quantities, and at short intervals. An exclusive milk diet will often be found most advantageous. Stimulants must be taken only in small quantities, and with the food. When symptoms of anæmia are present, *iron* may also be administered with the food. As a rule, the daily administration of iron to a patient with dilated heart is safe.

The patient should have the greatest amount possible of fresh air, and should be kept under the very best hygienic influences. The skin should be kept active, and slightly stimulating baths may be employed for the purpose of increasing the power of the capillary circulation.

To attain the second object, this class of patients must be placed under the strictest rules with regard to exercise. They should never allow themselves to be placed in such circumstances as to render necessary sudden and violent exercise, for a single violent physical exertion may jeopardize the life of any patient with cardiac dilatation. Every such exertion carries the point of resistance in the cardiac wall a little beyond what it can ever regain. Flannel should be worn next the skin. A dry bracing air, generally, agrees best with this class of patients. As regards the remedial agents to be employed in the management of cardiac dilatation, each case must be studied by itself. All exhausting discharges must be arrested. If hyperæmia of the liver and other abdominal viscera is present, it must be relieved by the occasional administration of an aloetic or mercurial purge. Excessive purgation, however, is not admissible, but a daily movement of the bowels, without exhausting catharsis, is important. When there is loss of appetite and impaired digestion, vegetable tonics and mineral acids are indicated. Those remedial agents which have a direct effect upon the heart itself are all-important in the management of this form of cardiac disease. The most important and most serviceable of this class of remedies is digitalis. It can always be administered in full doses, or at least in sufficiently large doses to regulate the heart's action. Often, when the feet become œdematous and the patient cyanotic, this remedy has a wonderful effect, and may often entirely remove, temporarily at least, all unpleasant symptoms. When the heart's action has been regulated by the use of the remedy, it may be continued in smaller doses, and the small doses should be continued for a long time. If, after a time, the heart's

action cannot be controlled by the digitalis, belladonna or opium may be combined with it. The effect of such combination is to tranquillize the excited heart; but the tranquillizing effect will be only temporary. This combination of remedies, then, should only be resorted to when the digitalis has been thoroughly tested and has failed. In the use of digitalis the same restriction should be observed which was mentioned in connection with the treatment of other cardiac diseases, namely, it should never be used indiscriminately, for the time will come, sooner or later, when the remedy will cease to have any controlling effect upon the heart, and then we are helpless. It is always desirable to postpone that period as long as possible.

Should the heart become nervously excited during the administration of the digitalis, as it often does, various antispasmodic remedies may be employed. Paroxysms of dyspnoea may be temporarily relieved by hydrocyanic acid, cannabis Indica, ether, and dry cupping along the spine. During the time when the disease is making slow progress, a great variety of measures may be indicated, and may afford temporary relief; but your chief reliance will always be upon digitalis and iron, associated with the most nutritious diet, and a careful avoidance of all excitement and undue physical exertion.

DIVIDED

TENDO-ACHILLIS WITH OPEN WOUND, SUCCESSFULLY TREATED, WITH COMPLETE UNION OF THE TWO CUT ENDS.

(A Paper read before the Northwestern, Ohio, Medical Association.)

By A. HURD, M.D.,

FINDLAY, OHIO.

Prof. Gross tells us that "Tendons, when divided subcutaneously, readily unite, through the intervention of plastic matter, without the occurrence of any considerable degree of inflammation." He also teaches that when a "tendon is divided in an open wound, the two ends rarely unite at all, owing mainly to two circumstances; the first is that the ends retract too far to enable us to bring them properly together; and the second, that the wound nearly always suppurates, an occurrence eminently inimical to adhesive action." There are three cases reported in the *MEDICAL RECORD*, in which perfect cures resulted. One in No. 206, by Prof. Kearney; one by Dr. G. H. Mitchell, in No. 202; and one by Dr. D. A. Sheffield, in No. 209. All of these, contrary to the general rule in such injuries, seemed to have resulted in a perfect reunion of the cut ends of the tendo-achillis.

As to the general management and the difference of opinion, as to the time required to repair the injury, I will refer you to the reports made by each surgeon, and also for the particulars of the treatment and the modes of procedure in each case. I have no doubt they are all of them genuine, reliable reports of actual cases, and that the facts are truly given as to the results obtained. Such good results, I am fully aware, are very exceptional. But I cannot see why, under proper treatment, with perfect coaptation of the divided ends, and the application of proper retentive apparatus, carefully and persistently used, we should fail in obtaining perfect cures. I believe coaptation of the cut ends can

be maintained by the use of proper apparatus and dressings carefully adjusted and carefully supervised after their application.

I propose to give the facts of a case of this injury which came under my observation, which corroborates the three cases referred to, and constitutes the fourth which has recently been reported of successful treatment of the injury:—

I was called, August 9th, 1874, to see C—N—, a little German boy, aged about 8 years, who had been wounded in the heel by a sharp stone (picked up from a newly macadamised street), thrown with great force by another lad. Upon reaching the patient, I found that the parents had dressed the wound, but had sent for me on account of the hemorrhage, which they were fearful would prove dangerous. On removing the dressing I found a transverse wound, a comparatively smooth cut, about one inch and a quarter in length, situated an inch and one-half above the insertion of the tendo-achillis into the os-calcis. When the blood had been washed away, I could see the lower end of the cut tendon protruding from the wound, and the upper end by retraction separated at least one inch from the lower end.

I could readily place my finger between the ends and distinctly feel the two cut ends completely separated, constituting a complete division, in an open wound of the tendon. Here was trouble. I had been taught, the weight of authority is in that direction—that complete reparation and union could not be expected, and rarely, if ever, occurred. There were two important indications to meet. Perfect coaptation of the ends, complete immobility and rest; the same requirements necessary to successfully treat fractured bones. The hemorrhage was mostly venous, probably from the wounding of the external Saphenous vein, and was readily asserted, which being done, and suitable appliances prepared, the patient was brought under the influence of chloroform, the wound thoroughly cleansed, care being taken to see that there were no small pieces of stone or dirt left in the wound. After which, while the leg was well flexed, the foot extended and firm pressure and extending force made by the hands of an assistant, upon the posterior muscles of the leg, I proceeded to put in three sutures of silver wire, through the integuments, the fascia, and the free ends of the tendon about one quarter of an inch from the edges of the wound, and by carefully though firmly drawing the wire, the ends of the tendon, and divided structures, were perfectly coapted. Adhesive straps were carefully applied, to relieve tension upon the sutures. The limb was now tightly and carefully bandaged, which was cut away over the wound to admit of inspection, and allow water dressing. A well padded splint reaching from little below the popliteal space down to the insertion of the upper sutures was applied, and firmly held in place by adhesive strips; to compress and prevent as much as possible the spasmodic action of the Gastrocnemius and Soleus muscles. Two small pads or compresses were placed over on either side of the cut tendon, and held there by straps of plaster to steady the ends of the tendon. To complete the dressing, I improvised Monroe's apparatus for maintaining flexion in ruptured tendo-Achillis, and carefully adjusted it to the limb. The boy was now placed in bed, and water dressing ordered to be applied if there was much heat or inflammatory action. The patient was carefully watched from day to day to see that the dressings were not too tight and the limb made painful from swelling. On the fifth day the dressings were removed, and the sutures taken out. The wound looks well, but little swelling,

scarcely any inflammation. The ends of the tendon are well together, and a part of the integument is healing by first intention. The bandages, splint, compresses, and apparatus are again applied, the same general directions given, with the same watchfulness over the case, and waited till the eighth day when the dressings are again removed. The wound is in good condition, but little inflammation has occurred. The integument healed except at the lower corner where the wound is open, and there is a discharge of pus; there is no fault in the coaptation of the ends of the tendon, everything looks favorable. The same dressings except the pads at the sides of the wound, are again applied. The wound is inspected and cleansed every day, when on the fifteenth day, the dressings are removed; wound is in good condition, not much inflammatory action, though discharging a small quantity of pus at same point, a hard ridge is noticed between the ends of the tendon, elevated, not depressed, showing the formation of plastic material, and that repair of the injury is taking place. The integument at one point being slightly adherent to the subjacent tissues, I left off all the dressings except adhesive straps over the wound and Monroe's apparatus, and still kept the patient quiet. Dressed the wound every day till the twentieth day, when it entirely healed externally, though there was tenderness at the point of the wound, with the same prominence. Still continued Monroe's apparatus, but let the boy move about on crutches.

On October 1st, fifty days after the reception of the injury, all dressing was laid aside and treatment discontinued. The wound was comparatively well; there was union by plastic material, of the cut ends of the tendon. He was permitted to walk about. Instead of a depression at the site of the wound there was an elevation. The cure seemed to be complete. The action of the muscles was natural. Nov. 25th, more than four months after the injury, he was attending school, no perceptible fault in walking. He can run as fast and as long as any of the boys. An examination to-day shows the ends of the tendon firmly united, with a hard lump at the point of the injury, possessing some of the characteristics of callous. In this instance the boy is ahead of old Achilles. He was struck by an arrow shot by Paris in the heel, his tendon cut, and he was slain. The stone thrown by the lad, cut this little fellow's tendon off, and he still lives and is well.

DECEMBER 23, 1874.

MODIFICATION OF FEHLING'S TEST FOR SUGAR IN THE URINE.—The *Medical Examiner* for December 1, 1874, contains an article by Dr. W. S. Haines, who claims that, for country practitioners, Fehling's test is unreliable from the fact that the test solution often decomposes. This fact is attributed to the impurity of two of the ingredients of the solution as usually obtained outside the large cities. These ingredients are the neutral tartrate of potash and caustic soda. For these, therefore, he substitutes glycerine and caustic potash, both of which can be more readily obtained in a state of sufficient purity to prevent the solution decomposing.

In this connection we would refer to a little manual by Dr. Austin Flint, Jr., published last year, and entitled, "Directions for the Examination of Urine of Applicants for Life Insurance." Dr. Flint also alludes to the fact that Fehling's test solution is apt to decompose when kept too long, but he observes that this may be entirely obviated by placing the different ingredients in separate solutions, which are only mixed together when required for use.

A CASE OF
ACUTE ARTICULAR RHEUMATISM WITH
PERICARDITIS, COMPLICATED BY
IDIOPATHIC TETANUS.

By EDWARD C. MANN, M.D.,

NEW YORK.

Mr. W., aged 20 years, a native of Germany, by occupation a laborer, applied for treatment Aug. 29th, 1874. He reported that he had been at work in a damp cellar, had been severely chilled, and when seen was suffering from an attack of acute articular rheumatism. He had previously had attacks of rheumatism and was liable to relapses upon sudden changes of the weather. When first seen, his pulse was 89° and the temperature in the axilla 103°. He complained of pain and tenderness in all his joints, and the joints were swollen and the skin reddened. The pain he complained of as being more severe in character than in previous attacks. The tongue was thickly coated and the bowels constipated. The specific gravity of the urine was high and it was of an unnaturally high color. The patient was put immediately upon alkaline with opium at bed-time, and a liniment of soap, chloroform and aconite was ordered to the affected joints. Aconite in small doses was also administered internally. At the end of the eighth day, the pain had nearly subsided, but the patient began to complain of pain and palpitation in the region of the heart. Warm anodyne infusions were ordered to the cardiac region, and the patient passed a moderately comfortable night. Upon inspection the next morning there was revealed a bulging of the cardiac region and percussion elicited an unnatural dullness at the root of the aorta. On the following day, the symptoms before noticed were much increased and the bulging of the cardiac region was more marked. As the pulse was frequent and small, the tinct. of digitalis in small doses was ordered and also stimulants to support the system. As the disease advanced percussion elicited an extension of the dullness to the second rib and beyond the right edge of the sternum. Auscultation revealed a nearly inaudible condition of the heart-sounds together with slight friction-sounds. The pulse became more frequent, and the temperature in the axilla had reached 105° when the patient complained of chilly sensations and a sense of uneasiness in the epigastrium. This sense of uneasiness increased and soon was complained of as pain, and as the patient exhibited great nervous agitation and restlessness, a dose of fifteen grains of hydrate of chloral, with one-sixth of a grain of morphine was administered, which resulted in the patient's passing a comfortable night. In the morning, however, the symptoms were more violent and the patient complained of difficulty in swallowing, owing to stiffness of the muscles of deglutition. The chilly sensations were also complained of as on the preceding evening. The difficulty of swallowing rapidly increased and the muscles of the jaw became very much contracted, causing inability to open the mouth. There were slight spasms, and, at times, partial opisthotonos, which was not as complete nor as well-marked, as in cases of traumatic tetanus. As the disease advanced an intense expression of anxiety characterized the features of the patient, and his eyes presented a widely staring appearance. The *alae nasi* were also dilated. The chloral and morphine as before was directed at bed-time, and ice was ordered to the spine. Conium, belladonna, and hypodermic injections of the alco-

holic extract of Calabar bean with the addition of water and glycerine, so prepared that twenty minims of the solution contained one-fifteenth grain of the alcoholic extract, were all used in turn, but with little mitigation of the nervous symptoms. The temperature steadily increased until it reached 108° degrees in the axilla, and the pulse, although rapid, was weak and compressible. There was marked wakefulness and great dyspnoea. The pupils were contracted, the walls of the abdomen were hard and froth escaped from the mouth. The patient complained once or twice of intense spasms of the heart, and at times manifested slight delirium. At the end of the sixth day from the development of the tetanus, the patient died in a state of exhaustion. Upon the appearance of tetanic spasms the patient being closely questioned denied having received any bruise or injury of any nature whatever, so that it was clearly a case of idiopathic tetanus, resulting from the exposure to cold and dampness, together with the combined depressing influence of the rheumatism and pericarditis.

A post-mortem examination being made, the body was found extremely rigid, and there was some oedema of the feet. The lungs and kidneys were somewhat congested. The spleen was normal. The pericardium contained a profuse sero-fibrinous exudation, and the surface of the heart and pericardium were somewhat roughened from the deposition of fibrine. There were also signs of some endocarditis. Upon examination of the brain and spinal cord, no inflammation was apparent, nor could any appreciable lesions be detected. A portion of the spinal cord was reserved for microscopical examination. This is a case of unusual rarity and interest, as idiopathic tetanus is a very rare disease, and there are but few cases on record of acute rheumatism complicated with pericarditis, presenting even tetanic convulsions, and, so far as can be ascertained, very few, if indeed any, in which the course of the tetanus has been so well marked. We are very much in the dark as yet regarding the pathology of tetanus, although we may reasonably infer that the lesions, while for the most part unappreciated, are to be referred to the gray matter of the spinal cord, and in idiopathic tetanus, also to functional disturbances of the nervous system.

A variety of opinions have been given regarding the pathology of tetanus, a few of which, in this connection, may not be out of place. Rokitsansky has found proliferation of connective-tissue in the spinal cord. Wedd reports congestion of a portion of the spinal cord. Curling says that there is serous effusion with increasing vascularity in the membranes, investing the medulla spinalis, and also a turgid state of the blood-vessels about the origin of the nerves, and Lockhart Clarke holds that we generally find granular degeneration of the cells of the spinal cord. Billroth, and the majority of the pathologists of the present day, on the other hand, have not found lesions in their examinations of the spinal cord and nerve.

However authorities may differ regarding the lesions accompanying tetanus, they are unanimous as regards an unfavorable prognosis. Dr. O'Beirne, in the Dublin Hospital, reports having witnessed 200 cases without a single recovery. McLeod, in his Notes on the Surgery of War in the Crimea, has collected 23 cases, in which but two recovered. Demme speaks of 86 cases in the hospitals of Italy during the war of 1859, of which six were cured. The only cases of idiopathic tetanus on record, have invariably resulted from exposure to cold and dampness. Watson states that Dr. Gregory, of Edinburgh, used to mention in his lectures the case of a man seen and treated by him, who having fallen

asleep in moist grass, awoke with a stiff neck, which afterwards developed into regular tetanus. Some years ago there was also reported a somewhat similar case of a man who suffered from well-made idiopathic tetanus arising from exposure to cold. The case was reported by Dr. Hall of Berwick.

It is easy to comprehend that an injury or irritant, however trivial, may, under certain circumstances and conditions of the nervous system, by acting upon the extremities of the peripheral nerves, produce in the spinal cord a state of excitement which results in the reflex spasms of tetanus; but as Niemeyer remarks, "We are completely in the dark as to the ways and means by which the lesions suffered by the cutaneous nerves in rheumatic tetanus is transmitted to the spinal marrow." With regard to the proportion of patients who recover from tetanus, the same author remarks, "Recovery is extremely rare. Transitory remissions, in which the patient may even enjoy a brief, refreshing slumber, should not be allowed to deceive us. After such pauses, the malady generally breaks out with all its former severity, or even with increased violence. We must not indulge in the hope of recovery unless the seizures continue to diminish in length, and frequently distinct relaxation of the contracted muscles during the intervals, and unless the patient become able to take food and nourishment. Even in the most fortunate cases this takes place with extreme slowness, and it is not until after the lapse of weeks that the muscles entirely lose their tension, and the patient is completely well."

Progress of Medical Science.

DIPHThERIC EXUDATION IN ENDOCARDITIS.—The case of which the following is a brief abstract is reported by Maier, as occurring at the Clinique in Freiburg. A man of 39, who had previously suffered from several attacks of pneumonia and pleurisy, was admitted into the hospital for an illness that had begun two or three weeks before with a chill and severe pain in the left side. Continuous fever had followed, with loss of appetite, diarrhoea, cough, and pain in the head. He died three days after admission. At the autopsy the free margins of the valves of the pulmonary artery, as well as the surfaces and margins of the aortic valves, were found to be somewhat thickened; while there was an ulcerated opening at the junction of two of the latter, leading to a canal which pierced the base of the interauricular septum, and communicated with the left auricle by a ragged orifice. The left kidney was shrunken and destroyed, while the right contained a large abscess, which communicated with the pelvis of the kidney. Examined by the microscope, the exudation on the ulcerated aortic valves was found to be identical with what is found in the mucous membrane of the pharynx in diphtheria, the characteristic elements being extremely small, shining, spherical granules in a mass of detritus. These bodies were not dissolved by ether, nor did they yield to solutions of caustic soda, nor were they colored by iodine or carmine as readily or deeply as the rest of the tissues. He regarded them, in fact, as independent organic forms, viz., the spherical form of the organisms known as bacteria. Few of these were found in the uriniferous tubules; but they were abundant in the capsules of the malpighian bodies. Maier recalls in this connection, the facts reported by Beckmann, who found the same bodies in the uriniferous tubules and

malpighian tufts in cases of puerperal and septic disease. Maier regarded the case as one of primary diphtheritic endocarditis, with secondary embolic processes in the kidney, of a septic character.—*Virchow's Archiv.*, Dec., 1874.

HYPODERMIC INJECTION OF ERGOT.—Dr. P. C. Williams reports three cases of postpartum hemorrhage treated successfully by means of the hypodermic injection of ergot. He advocates this method as prompt, safe and efficient. No abscesses or other bad effects resulted. He used the fluid extract, but also suggests using Squibb's solid extract for this purpose, the extract having been rubbed up with water in the proportion of a grain to the minim.—*St. Louis Medical and Surgical Jour.*, Dec., 1874.

PRIMARY TUBERCULOSIS OF THE FEMALE URO-GENITAL ORGANS.—Klebs says that tuberculosis of the mucous membrane of the bladder is very rare, and occurs exclusively in the male. Dr. Bang, however, relates a case occurring in Prof. Brande's division of the General Hospital of Copenhagen, which he believes is an exception to this rule.

The patient was a woman twenty-two years of age, with whom menstruation had commenced one year previously. Seven months before her admission into the hospital, she had pains in her back in the morning; shortly afterwards she was obliged to urinate frequently, and this act was accompanied by cutting pains in the urethra and over the symphysis pubis. At first there were no chest symptoms and the digestion was good. The urine was light, cloudy and offensive, slightly alkaline, and contained a little albumen, but no blood. The temperature increased gradually, and chest symptoms became somewhat pronounced. Colicky pains then occurred in the course of the right ureter, she became emaciated, and her appearance was more and more cachectic. Finally she had a severe cough and her ankles became oedematous. The post-mortem examination showed that in the duodenum there were two perforations which communicated with the right ureter. The ureter was about an inch in diameter for its whole length. The right kidney was very much enlarged, and had undergone what he regarded as tuberculous degeneration. There was only a little of the cortical substance remaining. The cavity was large and was filled with cheesy and purulent matter. The ureter had also undergone the same process of degeneration. At its lower end a large lump of caseous substance projected into the bladder. The mucous membrane of the latter had also participated, throughout its entire extent, in the same form of degeneration as the other organs. The left ureter was normal, except at its entrance into the bladder, where the mucous membrane was thickened. The lacunae of the vaginal mucous membrane were the seat of numerous small rosette-shaped ulcerations about the size of a pin's head.—*Hospitals-tidende*, 36, 1874.

A CERTAIN SIGN OF DEATH.—The most certain sign by which apparent death may be distinguished from real death, is held by Monteverdi to be the wine-red color of the skin, which is produced by a hypodermic injection of ammonia into the body. The theory on which this fact is founded is that the last act of human organic life consists in absorption. This function does not cease until after complete cessation of the capillary circulation. Liqueur ammoniac is the only reagent yet known, which is reliable as an indication of the activity or cessation of absorption, and, therefore, of the capillary circulation. The brightness and size of the resulting spot is a measure of the

vitality which still exists. In a dead body the injection does not produce any reddish discoloration of the skin whatever.—*Giorn. Ven. di Sci. Med.*, Sept., 1874.

CYSTERCERI IN THE BRAIN.—Giardiani relates the case of a peasant, twenty-five years of age, who was admitted into the hospital of Florence, with symptoms of mental alienation. There was no history of a hereditary tendency to mental disease. There were no febrile, gastric or abdominal symptoms to account for the culminating complication of the disease—the aversion to food. At first the patient spoke a few words, at intervals, but afterwards became mute, and at last broke out into acts of violence against his own person, directed principally against his own head. The radial pulse was 67, the temperature and respiration normal. Subsequently there were involuntary emissions of urine. At a consultation, the case was thought to be the slow nervous fever of Huxam, but on post-mortem examination, a hydatid cyst was found in the left ventricle of the cerebrum.—*L'Imparziale and Giorn. ven. d. Sci. Med.*, June, 1874.

HEMORRHOIDS TREATED WITH ERGOT.—Dr. G. W. Semple recommends the injection of ergot into the rectum for the treatment of hemorrhoids. A half fluid drachm of the extract was used in half an ounce of water. He refers to Langenbeck's method of injecting ergotin underneath the mucous coat of the rectum, but claims that his own method has the advantage of painlessness and facility of employment by the patient himself.—*Virginia Medical Monthly*, Nov., 1874.

ANÆSTHESIA BY INJECTION OF CHLORAL INTO THE VEINS.—Professors Deneffe and Van Wetter report seven new cases in which operations have been successfully performed under the anesthesia produced by the injection of chloral. They state that this plan has now been successfully tried in eighteen cases, and they give the details of the last seven, one of which was by Oré, of Bordeaux, the originator of the plan.

Oré's case was a young man, twenty years of age, from whom a tuberculous testicle was to be removed. The steps of the operation were substantially as follows: It was commenced at 8.43 A.M., at which time the median basilic vein was punctured, and one minute later 30 grains of chloral had been injected; after two minutes the patient appeared sleepy; the pulse was 112. At 8.51 A.M. there was complete insensibility, and the operation was commenced, lasting seven teen minutes. At 8.59 A.M. there appeared to be some difficulty in breathing, from the relaxation of the tongue, which blocked up the posterior portion of the buccal cavity. By raising the hyoid bone and passing a current over the left hypogastric, this condition was overcome. The amount of chloral injected was about 100 grains, and the injection lasted seven minutes, producing complete anesthesia, which lasted about an hour.

The patient remained in a deep sleep for fourteen and a half hours, during which time his sensibility was very obtuse. The respiration was always quiet and uniform, and there was no vomiting and no period of excitement. No irritation was observed at the place where the vein was punctured.

Another case was of a woman, forty-eight years of age, who was operated on for entropion. In this case 77 grains of chloral were injected into the median basilic vein, at the rate of about 7 grains every half minute. In four minutes and twenty-five seconds complete anesthesia of the cornea had been obtained with about 60 grains of chloral. Complete anesthesia lasted for forty-seven minutes, and sleep for seven hours. The results of the operation were also excel-

lent in this case, and, on the second day following, the patient was walking in the garden. The writers observe that in all these eighteen cases no serious disturbances of respiration have been noticed, which some have claimed take place when this experiment is tried on dogs. In one case, where the patient was very athletic, 150 grains of chloral were given in thirteen and a half minutes. There was no accident in this case, though the first urine passed was found to contain albumen and blood, so that really a slight hamaturia was produced, but this passed away and the patient did well. The writers remark that they observed less embarrassment in respiration when the solution of chloral was pretty fluid. They have generally used the solution in the strength of one to four of water, but they believe that when it was still more diluted the respiration and circulation were less affected.—*Bull. de l'Acad. Roy. de Med. de Belgique*, 10, 11, 1874.

THE PHYSIOLOGICAL ACTION OF JABORANDI.—Drs. Sydney Ringer and Alfred Gould, of London, have recently experimented upon the action of this new drug. It is found in the interior of Brazil and has been brought thence by Dr. Continho. It consists of the leaves and small branches of a shrub and has an agreeable and somewhat powerful aromatic odor. The dose is from thirty to ninety grains, infused in boiling water. These gentlemen confirm, in a great measure, the statements of M. Rabuteau as to its action on the skin, and they sum up their results as follows:

1. In three out of four cases, jaborandi caused profuse perspiration.
2. Jaborandi acted as a sialogogue, but was less certain in this respect than its diaphoretic effect.
3. In one case it increased the bronchial secretion.
4. It considerably accelerated the heart's action.
5. The temperature fell during its use.

Mr. Martindale, contrary to some high authorities, does not believe that jaborandi is composed of the leaves and stems of the pilocarpus pinnatifolius, and experiment with the latter seems to confirm his opinion.—*The Practitioner*, December, 1874.

ACTION OF CURARA ON THE WHITE BLOOD CORPUSCLES.—At a recent meeting of the Société de Biologie in Paris, Tarchanoff communicated the results of his researches on the action of curara. The following were his conclusions: If curara acts directly upon the white blood globules it destroys them; on frogs that have been curarized for two days, if the blood of the heart be examined, the white globules are found to have diminished very much in number, while the red globules have increased; the lymphatic spaces, however, are found distended and filled with the white globules. He believes that owing to the absence of muscular action, and under the influence of the increased tension of the capillaries, the white corpuscles accumulate in the lymphatic spaces, but when the action of the curara has subsided, muscular action has returned, and the tension in the vessels diminished, the lymphatic spaces close, the white globules reappear in the blood and the niphological composition of the fluid is again normal. The same phenomenon appeared under the following experiment. When it has been observed that the lymphatic spaces were distended with white corpuscles in a curarized frog, muscular movements were incited by the electric current, and the white corpuscles appeared again in the blood-vessels. He states that there is no destruction of the white blood corpuscles by curara as Dorsdorf asserts that this poison passes rapidly through the system, to be eliminated by the kidneys, and is found subsequently only in the bladder.—*Gaz. Hebdom.*, Dec., 1874.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

New York, January 16, 1875.

THE PARASITIC THEORY OF DIPH- THERIA.

THERE is hardly anything more welcome to the practitioner than the news that we have really found the cause of an insidious disease, that has contrived to defy our best directed efforts. It is a sad contemplation, however, for medical men, that in the great majority of such instances subsequent experience has either not verified the fact, or has shown that it allowed of another interpretation than the observers intended. And yet the agitation of these questions is desirable and is always conducive of good results, for it generally ends in the determination of some new data, that may at some time lead to the discovery of the true poisonous element of the disease. So it is impossible for any one to have watched the progress of medicine for the last few years, without feeling that we are gradually working our way nearer and nearer to the real source of disease, and that notwithstanding we have often failed to find this specific principle, we have at least discovered the conditions under which it lives and spreads. This can be said of typhoid fever, for it seems to be evident that filthy drinking water and the foul exhalations from sewers and privies are the principal agencies by which the disease is spread. That the real poison in all such infectious diseases may be a living one, has long been a favorite idea, both in this country and abroad, and efforts have been made to discover if they depend on a parasite in the sense that fævus is dependent on a fungus, and the itch on the itch mite. During the past few years, the number of the adherents of this parasitic theory has largely increased, and it is now claimed by some of them that several of the ordinary epidemic diseases have a parasitic origin. This is particularly true of diphtheria. The facts from which they draw their conclusions in the latter disease are so important, and have such a significant bearing on the treatment of the disease, that we will venture to state some of those

that appear to be the most worthy of notice. It is claimed, first of all, that the disease is communicated by contact, and plenty of evidence is brought forward to show that physicians and nurses have taken the disease by blowing through the tracheotomy tubes of the patients, or by having the diphtheritic matter accidentally coughed into their mouths; it is also claimed that the matter is inoculable on animals, and will produce in them a genuine diphtheria. It is admitted that the virus may not always be successfully inoculated, as in the case of Trousseau, although this fact does not disprove the theory, for vaccine matter often fails to take, and yet it undoubtedly contains a specific poison. Regarding this point as satisfactorily shown, and it certainly is in accordance with what we know of the general history of the disease, the adherents of this theory have tried to discover the specific element. We are told by Oertel, who is one of the authorities on this question, that in every form of diphtheria he found vast collections of minute, bright, round bodies, so small that they could barely be seen by lenses of high power, and to which he gave the name micrococci. He tells us that they increase in numbers as the disease increases in intensity, and when the disease is most active, and diminish in numbers when the disease abates; that they are found filling the lymphatic vessels leading to the glands in the neighborhood of the diseased parts, and in many cases block up the minute vessels and capillaries, especially in the kidney, which he tells us is an organ that is one of the earliest attacked. These minute organisms are regarded by him as the essential elements of the disease. Another German authority has gone so far as to separate these bodies from the various diseased tissues, and even from the urine of diphtheritic patients, and claims that these bacterial bodies, when used as inoculating material, have produced the disease in animals.

These are strong facts to be brought forward, and it is interesting to know what the opponents of the theory state. It must be observed that they do not attack the facts so much as the inferences drawn from them. They claim, in the first place, that the micrococci, as well as multitudes of other bacterial organisms, actually exist in the body in health. This fact is undoubtedly true, and any one who is familiar with the microscope has frequently seen bodies in the various tissues that almost exactly resemble them. In fact, it is admitted that they may be found in almost every one's mouth, about the teeth, and it has been asserted by some German authorities, that they are the cause of carious teeth; nor do they seem to be found simply in putrid fluids, but also, sometimes, in the blood during health. But the most damaging fact is, that these same micrococci have been found, in one instance, in the exudation on the cardiac valve of a puerperal woman who died of septicæmia and had no symptoms whatever of what we know as diphtheria. In a case of hospital gangrene, too, similar

bodies have been found, and the same is said of pyæmia.

If we take all these facts into consideration, and there seems to be no good reason for doubting most of them—for the observations appear to have been made with care—the present aspect of the case would appear to warrant us in concluding that the disease we know as diphtheria has not a peculiar parasite of its own, or else we shall have to enlarge our idea of diphtheria so as to include under it such other diseases as pyæmia, septicæmia, and hospital gangrene.

PROF. DALTON ON EXPERIMENTATION IN ITS RELATION TO VIVISECTION.

CONCERNING the necessity of vivisection there is no question with the profession. No body of men are better calculated to judge of its benefits, or more able to decide upon its influence in insuring progress in our art. With outsiders, however, the subject presents itself in an altogether different light, and it is a very easy thing to misconstrue motives, to misinterpret necessities, and look upon any physiological operation as a wanton piece of cruelty. We can hardly blame even educated non-professional people for entertaining such ideas, for ordinary humanity shrinks from any attempt at needless infliction of pain upon the lower creation, and it requires not a little stretch of enthusiasm for science to tolerate it. When, however, there arise men who pretend to be informed of all the necessities which bring the so-called cruelties into play, and who attempt to prove that all vivisections are not only needless to science, but are only the brutal exhibitions of heartless experimenters, it is time that all the facts of the case should be presented to the public. Such an attempt has been made by Prof. John C. Dalton, M.D. the author of the well-known work on Human Physiology. This gentleman has performed the task so well, that there is now no excuse on the part of legislators and the public at large for any want of the kind of knowledge they should possess, to be able to judge the merits of the case from a thoroughly impartial standpoint.

He gives a very interesting history of the influence of experimentation in determining the existence, character and uses of the different functions of the body, and has conclusively proven that without such experimentation we should be denied the benefits of some of the grandest triumphs of our art.

In regard to the charge that the infliction of pain is one of the invariable accompaniments of such operations, he says:

“In the few instances where the infliction of pain is a necessary part of the experiment, this pain is small in amount and momentary in duration. It would be an entire misapplication of terms to call it torture, or to apply to it the extravagant descriptions which have been sometimes employed. These are mostly cases in which the sensibility of a particular nerve or nervous centre is to be tested for a special purpose. In order

to obtain the requisite information, it is simply necessary to apply so much irritation as will reveal the presence or absence of sensibility in the part; and when this is done the work is accomplished. A slight irritation, if it succeed, is all-sufficient; and if a more violent one be necessary, it is because the sensibility of the part is deficient, and, of course, the amount of suffering is diminished to a similar degree. The same thing is often necessary in the treatment of the human patient, in cases of paralysis, in order to determine whether and to what extent the power of sensibility is affected by the disease.”

The necessity for experimentation on living animals is very clearly and forcibly presented. “If we desire to know anything,” says Dr. Dalton, “about the vital actions, it must be by investigation of the body during life;” in other words, post mortem dissection is a study of the human machine at rest, while vivisection is an investigation of the vital forces which control this machine when in full operation. As one of the most striking examples of this distinction, he refers to different properties belonging to the fifth and seventh pairs of nerves.

The charge of needless repetition of experiments is very well answered by a reference to the complicated functions of the pneumogastric. With apparently the same object in view, the experimenter is constantly interrogating nature in new directions. In fact, in all its complicated relations there is so much more to be learned, that experimenters are only just entering one of the most promising fields of physiological research. This is particularly true when we consider what an important relation this nerve bears to glycogenesis, and what light may yet be thrown, by a more thorough study of its functions, upon the pathology of diabetes.

It is unnecessary to follow the author through this *brochure*: suffice it to say, that he has left nothing undone to prove the great benefits to science which vivisection has conferred. It is one of the best written pamphlets of the day, and gives in a condensed and readable shape the histories of the discoveries, every one of which has marked an epoch in the history of medical progress.

In view of the threatened attempt on the part of the Society for the Prevention of Cruelty to Animals to expunge from the existing Act for the Prevention of Cruelty to Animals the clause, “excepting properly conducted scientific experiments or investigations,” this pamphlet, coming as it does from the one of the first physiologists of the country, is very timely. The last time the Humane Society made a similar attempt Dr. Dalton was influential in causing the exceptional clause to be inserted, and this time he is ready and willing to defend that action.

THE AMERICAN JOURNAL OF SYPHILOGRAPHY AND DERMATOLOGY.—The further publication of this journal—so its former publishers tell us—has been suspended.

Reviews and Notices of Books.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE. Edited by DR. H. VON ZIEMSEN. Vol. I. Acute Infectious Diseases. American Editor, Dr. Albert H. Buck, of New York. New York: William Wood & Co., 27 Great Jones Street. 1874.

RECENTLY, when we had the pleasant task of looking over the advance sheets of this magnificent work, we emphasized the masterly manner in which Liebermeister has presented the subject of the infectious diseases, and we called attention to the striking merits of his article on typhoid fever. The completed volume now lies before us, a handsome octavo of 708 pages, printed in a pleasantly large and clear type, and on excellent paper. We are glad to say that the work of translating has been done in a highly satisfactory manner, so that the difficulties of the foreign tongue have been successfully mastered, and the author's ideas are faithfully rendered in good English. Under the able editorial management of the American editor, Dr. Albert H. Buck, we find that each detail has been carefully supervised, while he has improved upon the German edition, by furnishing us with an excellent index and interesting biographical sketches of the different authors. We feel that we should be unfair if we left the subject of typhoid fever without adverting to the very practical deductions which come in at the close of the monograph, for while the scientific aspects of the disease are given a thorough and critical analysis, the treatment and prophylaxis receive hardly less attention. The methods he advocates follow naturally from the theories he maintains of the nature of the contagious principle, and the results that he gives, as obtained from his hospital experience in Basle, offer very good ground for sustaining the justness of this theory, and seem to demonstrate conclusively that the cold-water and quinine treatment is the most successful that has yet been offered to the medical profession. The author found, according to statistics, that 41 per cent. of the typhoid patients died from an excess of animal heat, while in the remainder the same influence was instrumental in producing the complications or the fatal result, and he believes accordingly that if the patients are guarded against the deleterious influences of excessive animal heat, typhoid fever will no longer be one of the very dangerous diseases. Accordingly, he has combated the excessive heat by anti-pyretic remedies, first among which comes *cold-water*. This form of treatment, he states, was first inaugurated by James Currie; but it had fallen into disuse until revived by Niemeyer, himself and others. It has, doubtless, a vast number of opponents, but their numbers are gradually decreasing in Germany, as the supposed dangers of the treatment are shown to be, for the most part, imaginary. Thus it has been claimed that it is likely to produce intestinal hemorrhage; but it is now shown by statistics that intestinal hemorrhage, as a complication, has materially diminished under the cold-water treatment, for since its introduction, the mortality has been $\frac{6}{10}$ per cent. as compared with $\frac{8}{10}$ before, and besides it is not so very fatal, for out of 127 such cases 78 had recovered, under his own observation. The author here alludes to the statements of Wunderlich, which not only sustain this idea, but even go farther and show, apparently, that intestinal hemorrhage is a circumstance which is apt to be dependent on the quality of the epidemic rather than any method of treatment.

The plan he recommends is always to suit the particular method to the wants of the case, and try and secure the desired result with the least inconvenience to the patient. Thus, for adults, he says, employ the *full length cold bath* of 68° Fahr. The duration of the exposure should be from five to ten minutes, varying with the strength of the patient. Perhaps, in some instances, it may be well to begin with a temperature as high as 95° Fahr., and then to lower it gradually to the required standard, by the addition of cold-water (Ziemssen's method). Employ the bath, he says, when the temperature in the rectum reaches 103° or in the axilla 102.2°. In children, however, it may not be necessary to resort to the bath until the temperature is about one degree higher. These baths should be continued at intervals, so that an average of from four to eight a day are given. In occasional instances they may be given every two hours, if the fever is very severe or obstinate. They are to be suspended when the temperature in the rectum reaches 101.5°.

The cold water treatment may also be carried out effectually by *cold affusions*, *cold packs*, *cold sponging*, and even by *cold drinks*. As to the use of quinine, the author was extremely skeptical as to its efficiency, until the results of Vogt were published in 1859. Following out the plan of this writer, he began giving quinine in large doses, so that from 22 to 45 grains of the sulphate or muriate were given daily. The following rules are laid down for the administration of the remedy, and he strongly insists on the necessity of carrying it out fully and to the letter. The daily amount is to be taken within the space of a half-hour, or, at the furthest, an hour, and he usually prescribes a powder of $7\frac{1}{2}$ grains every ten minutes, until the desired amount is taken. If quinine is given in even larger doses which are distributed over half a day, the effect on the temperature is often hardly perceptible, but if given in the way here directed the doses will not have to be repeated again for 24, and perhaps not for 48 hours.

The effect of these doses may be readily observed by the thermometer, for the temperature will commence to fall in a few hours, and it will continue falling gradually until from six to twelve hours have passed, when it will have reached the minimum. It will then gradually rise again, but usually will not reach as high a point upon the second day. The amount of the dose must be proportioned to the effect to be obtained, and the result will not be satisfactory unless the temperature is reduced to nearly the normal standard, that is, to 100.5° in the rectum. If this is not done by the first dose, the next must be increased. If, on the other hand, the first dose reduces the warmth to 98.5° or below, which is not uncommon, then the next dose is to be diminished. After the second week less quinine will be required to produce a given fall in the temperature. Occasionally digitalis may be given in combination with quinine, the best form being the substance, of which from 11 to 22 grains may be given so as to extend over a period of from 24 to 36 hours. The infusion is regarded as less effective. In attacks which resist the other methods of treatment, this plan often succeeds, especially if followed by from 30 to 45 grains of quinine. It should be understood that digitalis is only to be given in those cases where there is cardiac weakness, where the pulse has not yet become extremely frequent, or at least, is still tolerably strong. The rule for its application in typhoid is not the same as is commonly observed in many diseases of the heart, for the more frequent the pulse the less indication is there for digitalis. The

author also uses veratrin in some obstinate cases, but he believes that quinine, digitalis and the abstraction of heat by cold baths are among the most important antipyretic agencies, and are absolutely indispensable to the effective treatment of the fever. We naturally are eager to observe the results that are obtained in this way. The author states them as follows: formerly there was a mortality of 27 per cent. under indifferent, expectant, or symptomatic treatment; of 16 per cent. under an incomplete antipyretic treatment, while there is now a mortality of only 8 per cent. under a systematized antipyretic treatment. The antipyretic treatment therefore, is both logical, and is shown to be the most successful that has yet been offered to the medical profession.

As the *prophylaxis* of the disease involves our knowledge of the way in which it is propagated, the discussion of this subject forms an important topic in the article. According to the evidence we have at present, these are two principal media by which the specific germ or contagium is conveyed into the system. *Drinking water* is the most important of these and next come the *exhalations from privies or sewers*.

Instances are stated in which both of these agencies have spread the disease, and in some cases where it has been shown that the dejections of typhoid patients have contaminated the drinking-water or fouled the air, the fever has broken out with alarming virulence. On the other hand, when the drinking-water has been obtained from sources of undoubted purity and the dejections in privy vaults, etc., have been thoroughly disinfected, the disease has abated in a most marked manner. The deductions therefore are clear. Wells and all the sources of the water supply should be most carefully guarded from the possible admission of contaminating substances and all dejections from typhoid patients should be thoroughly disinfected. "This latter is easily accomplished," says the author, "by strewing the bottom of the vessel with a little sulphate of iron and then immediately after a passage crude muriatic acid is to be added so that it amounts to from one-half to one-third the bulk of the excreta." In this way the germs are destroyed. Much of this portion of the article will certainly have a very general interest, not for the practitioner only, but for the sanitarian, and it merits a most careful and attentive perusal for the interesting facts and valuable suggestions it contains. The translation, which is excellent, was done by Drs. Delafield and Shaufler.

The subjects of typhus fever, relapsing fever, bilious typhoid, and cholera next follow in order. They are from the pen of Prof. Lebert, and the translators are Drs. Van Harlingen, Fitz and Whittaker. Dr. Lebert, the author, has long been known to the profession as the author of "Lebert's Plates." His early works, including his "Physiologie Pathologique" were written in French during his residence in Paris. Latterly he has held a professorship in Breslau and his writings have been in German. We naturally expect to find him strong in pathology, for to this he has devoted the greater portion of his life. In his introduction he discusses the relation of minute organisms to disease, but he tells us that his researches on relapsing fever, typhus and cholera have been negative, except in the former, for he has been unable to find any organisms that could be shown to have any causal connection with the diseases: in relapsing-fever he believes that the spirilla discovered by Obermeier have a causal connection with the disease, inasmuch as he never failed to find them in the blood of the patients during the period of the fever.

In other cases he has been more successful. In 1846, he investigated the hospital gangrene of scrofulous ulcers observed in the Children's Hospital in Paris, and found that the entire tissue detritus of the ulcers was filled with myriads of moving bacteria. A somewhat similar disease was observed by him in frogs in 1856-8. He also investigated the silkworm disease, which caused such widespread calamity in certain portions of France, where the disease was found to be due to a minute fungus penetrating every tissue of the body, the egg as well as the fully-developed moth, and constituting the disease known as muscardine.

The author, however, states that he is non-committal in his general views on contagion and infection. He does not believe that the contagious or infectious principle is a chemical poison, for toxicology teaches us that there is no poison, organic or inorganic, that can attack and decimate entire populations. There may be, it is true, certain ferment poisons like those of hydrophobia which, introduced in small quantities, exert an intense influence over the system. It is not certain, however, that such a virus does not contain minute organisms. On the other hand, we have conclusive proof that certain diseases are of parasitic origin and the history of infectious diseases and the process of infection is in accordance with the theory of the existence of a *contagium vivum*. Yet he thinks the theory of parasitic infection cannot at present be adopted for the infectious diseases as a whole. The treatment is discussed at some length, but the author is evidently not sanguine as to the results of any special forms of treatment. In this respect, therefore, he will probably fail to meet the expectation of all. Yet he discusses these subjects with great care and thoroughness and shows that they have been the work of a scholarly and scientific practitioner.

The articles on the Plague and on Black Death are by Liebermeister. They are necessarily included in the list of acute infectious diseases, but they deservedly occupy but a short space, for they are of no interest to the general reader. The translation is by Dr. Normand Smith.

The article on Yellow Fever is by Dr. Haenisch, and is translated by Dr. Emerson. The author had, we understand, some unusual facilities for studying the disease in the West Indies; but we can hardly expect that the Germans can supply us with much information on a subject that is more properly our own and that can be of little practical importance to them.

The article on Dysentery is by Professor Heulmer, and is brief, concise, and well written, and gives a fair statement of the views now in vogue on this subject. It is translated by Dr. Putnam, of Boston.

Probably the article on Diphtheria, by Dr. Oertel, will be read with most interest. It is translated by Drs. Bridge, Stimson, and Emerson. It is probably the most thorough and exhaustive that has been written on the subject, and will repay careful study. The author claims that this disease is one of the oldest of the human race, though until the time of Brotonneau it was never accurately described. Prior to this time it was apt to be confounded with scarlatina, etc.; he did not, however, distinguish between croup and diphtheria, except that he regarded the latter as a higher expression of the former. Virchow taught that in diphtheritic inflammation there was an exudation into the substance of the mucous membrane, followed by mortification in this membrane from cessation in the supply of nourishment, while in croupous inflammation the exudation lay upon the surface. Wagner endeavored to prove that both were one and the same disease, but that croup never passed the bounds of the

local process. While these and similar discussions were going on, Hueter and Oertel observed that the diphtheritic membrane, the subjacent parts, and even the blood, contained low organisms, to which the name of *micrococci* was given. These little bodies are extremely minute, round, shining spheres that can just be recognized under lenses of high power. The author is careful to differentiate these bodies from the other parasites found in the body, and adopts the classification of Cohn, which seems now to be generally recognized by mycologists. Having observed that these micrococci were present in the diphtheritic exudations, lymphatic glands, blood, and kidneys, as well as in other organs of such patients, he proceeded to inoculate the exudation upon the cornea of animals, and obtained, he tells us, a diphtheritic keratitis. We are also told of a number of instances in which the attending physicians have lost their lives by direct contact with diphtheritic matter. On the other hand, in some instances inoculation experiments have not succeeded, though this cannot be regarded as invalidating his theory, for the same is true of all specific poisons. The author also believes that he has demonstrated that the disease is at first a local one, and radiating from this point, becomes a general infection of the whole body. The other theory is, that it is a general infectious disease, which secondarily localizes itself upon the mucous membrane of the throat.

Probably the most important argument in favor of the author's theory is, that these organisms have been found in the vasa afferentia of lymphatic glands in the neighborhood of the diphtheritic exudations, in some instances almost completely filling the vessels; also in the kidneys at every stage of the disease, and in various other organs. Another argument that will carry weight is, that while many forms of parasites are present in the exudations during the early periods of the disease, it is the micrococcus and bacterium termo that multiply with the greatest rapidity and are found subsequently in the affected tissues during the height of the disease; during convalescence, these forms diminish in number and are superseded by the ordinary forms commonly found in the system. Again, we are told that the intensity of the infection is proportionate to the degree in which the tissues are invaded by these organisms.

The author states his views positively, believing with Eberth, that without micrococci there can be no diphtheria, and that "they are inseparable from the diphtheritic process, just as the bacteria of decomposition are necessarily connected with decay and act as a ferment." Perhaps these facts are indisputable, and many observations appear to sustain them; and yet it does not appear that these organisms are found alone in the disease which we, in this country, regard clinically as diphtheria. This subject is one of such great importance that it is to be hoped further inquiry will be made into it.

Space will not permit us to sketch the plan of treatment recommended, and which will be read with interest because of its thoroughness. The author expresses himself as most decidedly opposed to cauterizations, astringent gargles, and the like, and finds the greatest advantages are obtained from the vapor of hot steam, and gives excellent reasons for so doing; a supporting treatment is necessary to sustain the system against the prostration which accompanies the general infection. This article closes the book. In conclusion we state unhesitatingly, that if this volume is the type of those that follow, the Cyclopædia will certainly be the most valuable contribution to the sub-

ject of internal medicine that has yet appeared, and will mark an important era in the present progress of medicine.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 23, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

ANEURISM OF AORTA—LARYNGOTOMY, WITH TEMPORARY RELIEF.

DR. JANEWAY presented the larynx, heart, aorta, and lungs removed from a man who was admitted to Bellevue Hospital, Dec. 19, 1874, and who gave the history that he was about 33 years of age, and had had attacks of difficult breathing for six weeks previous to his admission; that these attacks had been accompanied by some hoarseness, and he had had some hoarseness in the intermediate time. Three or four days previous to admission he suffered from very severe attacks of dyspnoea, and it was to obtain relief from this symptom that he sought admission to the hospital. Upon admission, he was in the extreme state of dyspnoea. An examination with the laryngoscope was made with considerable difficulty, when it was discovered that there was almost complete paralysis of the left vocal cord. This condition, taken in connection with the fact that he had had paroxysmal dyspnoea, without any condition of lung to account for it, made the diagnosis probable that an aneurism was pressing upon the left recurrent laryngeal nerve; and that the aneurism probably was not large for the reason that there was no murmur, nor well-marked dulness accompanying it. The condition of the patient, however, would not permit a thorough examination.

Laryngotomy was directed in case the attacks of dyspnoea became more alarming, and in the night of the same day the operation was performed by Dr. Knox, then acting house-physician. A small quantity of blood entered the larynx, but was sucked out through a catheter. After the operation the man became quiet, face assumed almost the normal appearance, and his voice returned when the larynx became cleared.

During the night other attacks of dyspnoea came on, accompanied by stridulous inspiration and expiration as before. The operation, however, produced temporary relief, and life was probably prolonged nearly twenty hours.

The *post-mortem* revealed an aneurism springing from the back part of the transverse arch of the aorta, with some little widening of the vessel at the junction of the ascending with the transverse arch. The aneurismal sac pressed back upon the trachea, and reached as far as the left subclavian. The pneumogastric nerve was found bound down by some newly formed connective tissue. The recurrent nerve was found upon the top of the tumor, and also bound down. Both nerves, therefore, were found involved in the tumor. Upon the inner surface of the trachea, on the left wall, just above the bifurcation, and reaching just to the upper part of the left bronchus, was a small ovoid tumor about an inch and a half in length, which almost occluded the trachea. It was the wall of the trachea which had yielded to the pressure of the aneurism. It was noticeable that the opposite wall of the trachea had been arched out so as to make room for the pas-

sage of air. This tumor was elevated about half an inch above the inner surface of the trachea.

There was, then, pressure upon the recurrent and pneumogastric nerves; pressure upon the trachea, and somewhat upon the left bronchus, but without complete obstruction of either. The doctor remarked that he had seen the operation of laryngotomy performed several times for the purpose of obtaining relief from pressure upon the recurrent nerve in cases of aneurism, but in no case had life lasted longer than a week. The prolongation to life, however, has been sufficient to warrant the operation, and it is justifiable even if life is prolonged only a few hours. The kidneys showed evidences of Bright's disease.

Dr. Janeway also exhibited a specimen of blood taken from a patient suffering with leucocythemia. The spleen of the patient is enlarged, extending twelve inches in the longitudinal direction, and ten inches in the transverse. The globules measured from $\frac{1}{1000}$ to $\frac{1}{2000}$ of an inch in diameter, and were present in the proportion of about 1 in 10.

DR. KNAPP presented a specimen of medullar cancer of the retina. After which the Society adjourned.

NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

Annual Meeting, December 21, 1874.

THE PRESIDENT, DR. MEREDETH CLYMER, in the Chair.

MOTORIAL FUNCTIONS OF CEREBRAL CONVOLUTIONS.

DR. ALLAN McLANE HAMILTON presented a new form of Dynamometer devised by him.

DR. JOHN C. DALTON presented the Report of the Special Committee upon "Experimental Researches on the Motorial Functions of the Cerebral Convolution." The experiments on which the report were based was performed on five dogs, weighing each from five to eleven kilogrammes, anaesthesia being more or less complete. A portion of the eranium and dura mater was removed on one or both sides over the hemispheres, and the exposed surface stimulated at different points by a galvanic current generated by from eight to sixteen zinc-carbon elements, immersed in a solution of bichromate of potassium and dilute sulphuric acid, the electrodes being usually applied one millimeter apart. This strength of current, barely perceptible on the cheek and not painful on the tongue, was thought to give more precise results than those by a more powerful current. The electrodes were applied for about one second. Twice they were applied alternately to the dura mater and to the surface of the brain, and difference in effects noted. After a particular spot had been found where the application of the electrodes caused a distinct muscular contraction, it was repeated until a slight brownish discoloration appeared, and then its site was fixed by the insertion of a pin. The animal was then killed and the brain kept in spirit.

Details of numerous experiments were given and the brains exhibited, with the pins *in situ*. The observations of the committee confirmed the most important of the results of Hitzig's experiments and those who followed him. There is no doubt that these certain limited areas on the surface of the cerebral convolutions where galvanic excitation will cause distinct momentary contraction of separate muscles or groups of muscles on the opposite side of the body, whilst similar excitation of other points not more than 5 mm. distant will be without effect. There appears to be correspondence of function in similar points of

both hemispheres, though this cannot be positively stated, the two sides of the dog's brain never being wholly symmetrical, as regards fissures and convolutions. An apparent exception exists in a special point, which, when excited, was followed by flexion of the head and neck: both sets of muscles, either right or left, either acting together, or else each one showing the power to flex the head without causing lateral deviation. "All the centres of motion for the anterior and posterior limbs are situated in the convolution immediately surrounding the frontal fissure, so well marked in the dog, and running outwards from the median fissure, and situated about the junction of the anterior and middle thirds of the brain, as seen from above. The centres for extension and flexion of the anterior and posterior limbs were always found in the external part of the pre-frontal convolution, just anterior to this fissure, and in the post-frontal convolution just behind it. In most instances those for the fore-limbs were more in front, near the outer extremity of the frontal fissure, and those for the hind limbs more posteriorly and inward, but the exact site varied a little in different experiments. The centre for flexion of the head and neck in the median line is in the lateral and anterior part of the pre-frontal convolution, where it bends downward and outward. That for flexion, with rotation toward the side of the stimulus, is in a part of the convolution situated still further toward the front and downward, invisible in a view of the brain from above. The centre for the facial muscles is in the lateral part of the hemisphere immediately about the supra-sylvian fissure. These results correspond nearly exactly with those of Hitzig.

The committee was not able to indicate precisely the motor points for flexion and extension of the fore and hind limbs respectively, for in some cases their position varied more or less in the different animals, and in some a single application of the electrodes would produce movements in more than one set of muscles.

The committee are led to the conclusion, that centres of motion in the cerebral convolutions exist, and that when the galvanic stimulus is applied only and exactly to the centres, movements will follow peculiar to themselves. The report was accepted, and, on motion, the discussion was postponed to the next meeting.

DR. E. G. LORING, JR., read a paper on "The Retinal Circulation and the Mechanical Causes of Choked Disk," which was largely illustrated. It was shown that the general circulation might be profoundly affected, by drugs, electricity or mechanical interference, as by ligature of the vessels of the brain, and yet the circulation of the eye remain uninfluenced, or very slightly. Now, either the circulation of the eye is not a reflex of that of the brain, though directly derived from it; or if the retinal circulation be a reflex of the cerebral, then it follows that the influence exerted on the circulation of the brain by direct agents is very much less than hitherto supposed. From the similarity of the physical conditions and arrangement of the circulation of the eye and that of the brain, the question arose whether there was any pulsation of the cerebral arteries, and reasons were given for inferring that as there was no pulsation in the arterial circulation of the eye, there ought, by analogy, to be very little in the cerebral.

Græfe's theory of the production of choked disk by increased intra cranial pressure, and Benedict's hypothesis of a neuro-paralytic origin, were reviewed, as well as the Schwalbe-Schmidt's—which assigns as cause the passage of fluid from the arachnoid space between the outer and inner sheaths of the optic nerve. The consideration of the several views leads to the con-

clusion that Benedict's theory is the least assailable, because, perhaps, the least demonstrable.

In the discussion which followed, Dr. NOYES thought we were not yet on solid ground. The theory of extension of fluid from the brain was not proved, yet such extension had been clearly shown in some autopsies. Most autopsies show fluid at the ocular and not at the cerebral end of the nerve. As the nerve approaches the eye is increased by the accession of vessels, and about its entrance into the ball a vascular ring is formed. It is to be remembered that the nerve can only find room for expansion in the longitudinal direction. Caution is necessary in deducing cerebral conditions from examination of the ocular end of the optic nerve.

DR. DERBY showed drawings made by Dr. Norris, of Philadelphia, illustrating a case referred to in Dr. Loring's paper. He thought the unreliability of the ophthalmoscope in the diagnosis of cerebral hyperemia and anemia was conclusively proved.

DR. KNAPP remarked that we must discriminate between two forms of choked disk: that from neuritis ascends with inflammatory action in nerve or sheath and distinct elevation of disk, and that wherein fluid exists between the layers of the optic sheath, blood may sometimes ooze from the brain through the intervaginal space into the eye. There is considerable space between the optic nerve and the optic foramen. He believed, with few exceptions neuro-retinitis pointed to cerebral disease.

DR. DALTON regarded the absence of arterial pulse in the eyeball as a remarkable fact, and pulsation in the veins under abnormal conditions as more incomprehensible. We may, perhaps, explain the non-pulsation of the arteries, but not the pulsation of the veins.

DR. LORING could only suggest as an explanation that the arterial walls were more elastic and denser than those of the veins.

DR. J. J. MASON could confirm Dr. Loring's observations on the lack of effect of galvanization of the cervical sympathetic upon the retinal circulation.

The Society went into Executive Session for the election of officers for the ensuing year, and adjourned.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from January 3rd to January 9th, 1875.

KINSMAN, J. H., Assistant Surgeon.—Assigned to duty at Fort Abraham, Lincoln. D. T. S. O. 284, Department of Dakota, Dec. 30, 1874.

WHITE, R. X., Assistant Surgeon.—Relieved from duty in the Department of the Gulf, and to rejoin his proper station in the Medical Division of the Atlantic. S. O. 278, A. G. O., Dec. 30, 1874.

WIGGIN, A. W., Assistant Surgeon.—Relieved from duty in Department of the Columbia, to report in person to the President of the Army Medical Board, at New York City, for examination for promotion, and upon its completion, by letter to the Surgeon-General. S. O. 3, A. G. O., January 6, 1875.

THE SMALL-POX HOSPITAL, on Blackwell's Island, has been transferred by the Commissioners of Public Charities and Corrections to the jurisdiction of the Board of Health.

The Commissioners have also resolved to designate one day of the week when the steamer *Bellevue* should carry poor passengers between the City and the Island institutions free of charge.

Medical Items and News.

PROF. BENJAMIN G. WILDER will give the course on physiology in the Medical School of Maine at the next term. DR. EDWIN BANTLY, U. S. A., has been appointed resident physician of the Insane Asylum, at Napa, Cal. DR. LOMBE ATTHILL has been elected President of the Dublin Obstetrical Society. Prof. T. GAILLARD THOMAS's work on the Diseases of Women is being published in Spanish by D. Appleton & Co.

A SINGULAR LIBEL SUIT.—Dr. Baird, of Daylesford, Australia, sued the town-clerk for £100 damages for having spoken of him as a "bounding medical kangaroo." The judge thought the phrase might be considered rather complimentary than otherwise, and the plaintiff was nonsuited with costs.

A HYGIENIC INSTITUTE is to be erected at Munich, to be placed under the directorship of Professor von Pettenkofer.

ACADEMY OF MEDICINE.—At the meeting of the Academy of Medicine, held on the 7th inst., the following officers and members of committees were elected:—*President*, Dr. S. S. Purple; *Vice-President*, Dr. Gouverneur M. Smith; *Trustee*, Austin Flint, sen. *Committee on Admissions*, Dr. M. Blumenthal; *Committee on Medical Ethics*, Dr. T. M. Cheesman; *Committee on Medical Education*, Dr. E. R. Peaslee.

The Academy has acquired a title to the house No. 12 West Thirty-first St. The building is twenty-eight feet wide by sixty to sixty-five feet in depth, and is said to be well adapted to the purposes of the Society. The necessary alterations will not be possible before May, and it will not be ready for occupation before fall.

DR. FRIEDRICH ROCHLEDER, Prof. of Chemistry in the University of Vienna, died Nov. 6, 1874.

DR. WILLIAM MARSDEN, of Quebec, has been elected President of the Society for the Prevention of Cruelty to Animals in that city.

THE BOSTON MEDICAL AND SURGICAL JOURNAL commences its ninety-second volume with a new departure, its proprietorship having been transferred from David Clapp & Son, its former publishers, to the Editors. It is now published in, a much improved style, by H. O. Houghton & Co.

THE ALBANY MEDICAL COLLEGE recently graduated forty-seven students—the largest class the institution has yet had. Governor Dix made the address, and, among other remarks, suggested that the preservation of health should be as studious a care to them as the cure of disease.

ELEPHANTIASIS IN CANADA.—According to the *Toronto Globe*, there have been lepers for the last eighty or ninety years near the mouth of the Miramichi River.

THE STUDENTS AT ST. PETERSBURG are stated to be in rebellion against Professor Cyon on account of the strictness of his examinations.

PROF. HUXLEY is to undertake the duties of the Chair of Natural History in the University of Edinburgh during the ensuing summer session, in the absence of Prof. Wyville Thomson, who is with the Challenger Surveying Expedition.

DELINQUENT SUBSCRIBERS.—The last number of *The Doctor* contains a notice that it will publish the names of all subscribers who persistently neglect to settle their subscriptions.

DR. JAMES VAN ZANDT BLANEY, late Professor of Analytical Chemistry, who recently died in Chicago, was born at Newcastle, Delaware, May 1st, 1820. His death resulted from an organic disease of the liver, which had troubled him for the past two years, not assuming an aggravated form, however, until about six months ago. He graduated at Princeton, and received his medical education at the University of Pennsylvania. He was a pupil of Professor Henry, at the Smithsonian Institute, ably assisting that gentleman in his chemical laboratory. He removed to Chicago thirty years ago. In connection with Professor Brainard, he founded the Rush Medical College, and upon the death of President Brainard, in 1866, succeeded him, filling the position until compelled by ill-health to resign, some three or four years ago. He also founded the Chicago *Medical Journal*, and ably edited it for some time. He was looked upon as the most distinguished chemist in the Northwest, and he was also a skilful physician. He was at one time Professor of Chemistry in the Northwestern University, and was also Medical Director in connection with several departments of the Union army in Virginia. He occupied this position on the staff of General Sheridan at the battle of Winchester, and took charge of the wounded in the hospitals. Dr. Blaney was married July 8th, 1847, to Miss Clarissa Butler, niece of Benjamin F. Butler, of New York, who was Secretary of War during Van Buren's administration.

PERCY—Suddenly, of apoplexy, at his late residence in Brooklyn, N. Y., on Monday evening, January 4, 1875, Dr. Edward R. Percy, in the fifty-seventh year of his age.

THE CHOLERA AND THE PLAGUE.—The Turkish Government has sent Dr. Arif Bey, Vice-President of the General Board of Health for the Empire, to Mecca, to make preparations against an outbreak of cholera among the pilgrims who will shortly congregate there. The reason of this precaution is the report of the ravages of cholera in the Dutch possessions in the Indian Archipelago, from which settlements large numbers of pilgrims are expected. The cholera of 1865, which spread through Europe and America, was, the Turkish authorities believe, brought by pilgrims from the Indian Ocean. The plague, after an absence of fifty years, has broken out near Mecca. Dr. Charles Müllingen, of Constantinople, has been sent to the infected locality. The plague is now believed to be a malignant form of typhus fever. This theory is confirmed by the investigations of the late Dr. Lavel, a French Surgeon-Major, who recently lost his life while studying this epidemic in Tunis, where it has also appeared.

THE LONDON HOSPITAL SUNDAY FUND.—At a meeting of the Trustees of the London Hospital Sunday Fund, which was held December 16, the gross receipts for the year were stated to be £29,678, which sum is £2,000 greater than the collection of the preceding year. Of this amount £25,307 has been given to fifty-four general and special hospitals and eight institutions, and £3,040 to forty-five dispensaries. A committee was appointed to prepare a rule for the granting of the funds. June 13 was appointed as the Hospital Sunday for this year.

THE PROTECTION OF THE POSTAL RIGHTS OF THE INSANE.—The House Postal Committee to-day agreed to report favorably Mr. Hawley's bill for the protection of the postal rights of the inmates of insane asylums, with an amendment that all letters coming from insane asylums shall bear on the envelope the name of the asylum from which sent. An earnest advocate of the bill was Miss Packard, of Chicago, who said that many

persons were held in insane asylums who were perfectly rational, and would be released if they had the facilities for communicating with their friends. She cited her own case as an illustration, she having been long detained, although she was entirely sane. She also made a statement that there were many inmates of insane asylums committed on account of religious enthusiasm who were perfectly sane, or became so after treatment in a very short time.

SMALL-POX IN ELIZABETH.—The first genuine case of small-pox that has been reported in this city this winter was discovered on the 2d inst. The person was a German baker, and continued to deal out bread to customers after the disease had made its appearance.

THE USE OF THE MOSQUITO.—Dr. Samuel W. Francis says, that this insect was created to drive man from malarial districts; and second, if man will not go, after the warning is given in humming accents, then the mosquito injects hypodermically a little liquid, which answers two purposes—firstly, to render the blood thin enough to be drawn up through its tube; and, secondly, in order to inject that which possesses the principles of *quinine*.

CHARITY HOSPITAL.—DRS. F. N. Otis, Robert W. Taylor and W. H. Van Wyck have recently been appointed to the Visiting Board.

THE RIGHT MAN IN THE RIGHT PLACE.—The post of head apothecary to the Paris *Assistance Publique* has been obtained by a gentleman possessing the appropriate cognomen of *M. L'Extrait*.

DR. S. OAKLEY VANDERPOEL, Health Officer of the port, is delivering a series of lectures on Hygiene at the Bellevue Hospital Medical College.

BRONZE STATUE OF A PHILANTHROPIST.—Mrs. Bartlett's statue of Dr. Wells, the discoverer of anaesthesia, is to be cast in bronze, in one piece, and set up at Hartford, just as it comes from the mould.

DR. B. FORDYCE BARKER has been appointed Visiting Physician to the Woman's Hospital, *vice* Dr. J. Marion Sims resigned.

PROF. FRANK H. HAMILTON gave a reception at his house on Tuesday evening, to Dr. S. Oakley Vanderpoel, Health Officer, and Dr. John P. Gray, Medical Superintendent of the State Asylum, Utica. A large number of distinguished gentlemen were present, and altogether the affair was the most enjoyable one of the season.

GOTTFRIED MAYER, M.D.—Died, January 4, 1875, Gottfried Mayer, M.D., aged 43 years, at 54 Meserole Ave., Brooklyn, of pleuro-pneumonia, after three days sickness.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, January 18th.—Obstetrical Section of the Academy of Medicine; Medico-Chirurgical Society; N. Y. Society of Neurology and Electrology; Pathological Society of Brooklyn.

Tuesday, January 19th.—N. Y. Obstetrical Society; Dermatological Society; N.-W. Medical and Surgical Society; Medical Society of the County of Kings (annual meeting).

Thursday, January 21st.—N. Y. Academy of Medicine; Medical Association of the Eastern District of Brooklyn (election)

Friday, January 22d.—Medical Library and Journal Association; "A Historical Sketch of the Origin and Progress of the Medical Library and Journal Association of New York." Dr. John C. Peters.

Saturday, January 23d.—N. Y. Medical and Surgical Society (annual meeting)

Medical Department of Life Insurance.

ADDITIONAL THOUGHTS CONCERNING INEBRIETY AND LIFE INSURANCE.

By WILLIAM C. WEY, M.D.,

ELMIRA, NEW YORK.

In the examination of applicants for life insurance, one of the most difficult tasks of the physician is to determine if the person before him is addicted to the use of intoxicating liquor. The family history, summarized in the usual manner, imparts no information respecting an inherited tendency to inebriety, and the replies of the applicant to the question concerning his habits are meaningless and unsatisfactory. It becomes necessary, therefore, to protect life insurance companies from undue hazard, to learn if possible if an applicant is an occasional or an every-day drinker, and to what extent his indulgence has affected his health, and made its influence visible by such tests as reveal morbid phenomena to the careful scrutiny of the physician.

It may be said, as a rule, that the long-continued use of alcoholic liquors furnishes unmistakable signs of physical deterioration. That excessive indulgence impairs the mental and physical energies is painfully evident, even to the most casual observer. The protracted employment of stimulants, measured by a nice regard of physical needs and peculiarities, has not unfrequently been the means of prolonging life, and endowing feeble organizations with capacity to bear the burdens under which they would otherwise certainly be crushed. So jealous, however, is the public mind, and so watchful the medical profession of the power and extent of the alcohol habit, that the indulgence mentioned would arouse earnest reprobation as a hygienic measure on the one hand, or as a reason for continuing a lease of life, in which an insurance corporation might be disposed to derive prospective advantage on the other. According to the first estimate the license of a simple hygienic plan would be likely to degenerate into an uncontrollable habit. The second estimate, viewed in the cautious analytical manner, peculiar to business, involves so many hazards as to preclude the possibility of regarding the moderate use of alcohol as conducive to long life.

The fact is apparent to medical and lay observation, that risks in life insurance are constantly being taken, in which alcoholic indulgence, to a less or greater degree, proves a factor in the chances assumed by corporations, even though all ordinary care may be exercised to exclude the semblance of inebriety from participation in the contract. The personal habits of an applicant may not be known, much less suspected. His indulgence in the use of alcohol may be secret, though limited, which is the most subtle and dangerous form of the inebriate habit; or it may be social and occasional, and confined to a brotherhood of good-fellowship, whose acts are sedulously concealed from the outside world. Thus far, perhaps, the signs of inebriety, or, to express it more correctly, the indications that an inebriate habit is in process of formation, are not apparent. The mental powers are not implicated and the physical man preserves its normal integrity. Inebriety has not assisted its dominion by a single sign that can be recognized or understood, and yet its seeds are finding soil which sooner or later will insure development into an abundance of sorrowful, mental, moral, and corporeal results.

As there is a condition of the body preceding the formation of tubercle in the lung-tissue, known as the pre-tubercular stage of phthisis, whose phenomena are not known or appreciated, in the same way an indolent tendency may imperceptibly germinate, when as yet its beginning and progress are not suspected by any appreciable indications. In this connection we discard the consideration of inherited inebriety and the family history, and regard the case as hypothetical merely; of course, no delicate act of the physician is capable of perceiving this condition, either as a study of disease, or as a means of preserving life insurance companies from the ulterior consequences of the inebriate state. The insurance of life accepts this contingency, just as it accepts undeveloped consumption or cancer, or such rare forms of disease as angina pectoris or dry gangrene.

The average number of men who die of consumption in every settled community is correctly known, and the laws by which that disease is transmitted, and the period in life at which its invasion is expected have been demonstrated with such accuracy as to prove of incalculable service to insurance companies, in the contemplation of hazard and loss, in the business of dealing with questions of expectancy of life. The same remark applies to many other forms of disease. It applies to insanity in its multiform exhibitions, and the statistics concerning this form of disease are regarded as reliable, simply for the reason that they have been furnished as the results of individual observation and experience, and grouped together in such a manner as to carry conviction of their credibility.

It is to be regretted that we cannot as fully believe the statistics so frequently published on the subject of drunkenness. We are aware of certain facts concerning the alarming prevalence of the alcohol habit. We see every day the consequences of inebriate indulgence, in the production of crime, poverty, vagrancy, disease and death. All are acquainted, even the children of our households, with the ordinary signs of intoxication, as exhibited in the streets, and we come to look upon such scenes with indifference, because of their constant repetition. Convinced that intemperance, directly and remotely, enters largely into the mortality of our people, we look in vain for confirmation of this belief in the published mortuary records. As an illustration of the unreliability of such statements, in connection with the subject of drunkenness, I have examined the death-tables for the city of Elmira, from June, 1867, when they were first given to the public through the efforts of the Academy of Medicine, a local organization, to the present time, with the following results: Two thousand and eighty deaths have occurred. "Delirium tremens" proved fatal in six cases, "inebriety" in two, "drunken apoplexy" in two, and "alcoholism" and "dipsomania" in one each—making a total of twelve deaths from all causes connected with drunkenness, or *one in one hundred and seventy-three*. Consumption, in the same time, destroyed 242, or 1 in 8.—Typhoid fever 86, or 1 in 24. Accidents of all kinds 84, or 1 in 26. Cancer 52, or 1 in 39. Scarlet fever and disease of the heart, 45 each, or 1 in 46, and whooping-cough 39, or 1 in 53.

Here we see unmistakable proof of an endeavor on the part of medical attendants and friends to conceal the cause of death among inebriates. In a few cases only the truth was expressed, doubtless for the reason that no purpose could be subserved by withholding it, such as family affection, pride, charity, or other like consideration. A drunken pauper is usually consigned to the grave with little ceremony, and with no circumlocution of terms to express the manner of his depart-

ure. A drunken man, with friends and property, is carried to the tomb as the victim of congestion of the brain, gastric fever, chronic dyspepsia, Bright's disease, paralysis, epilepsy, dropsy, remittent fever, or enlarged liver. I have known certificates of death from these causes to be given in cases of chronic alcoholism, not because the specific affections cited had actually occurred as secondary features of the inebriate habit, but merely for the sake of diverting attention from the nature of the infirmity in question.

On the part of friends, and with the drunkard himself, a disposition is generally manifested to make light of the habit which has asserted its authority in the system. Hence the unwillingness to acknowledge a growing disposition to use spirituous liquors, in a person seeking life-insurance, and his positive denial of a fixed habit of indulgence. A delusion appears to accompany the formative stage of the inebriate habit, especially when acquired through solitary gratification, that no evidence of the immediate effects of indulgence, and no fear of the ultimate supremacy of the power of alcohol over mind and body is discoverable to the public, or the constant watchfulness of relatives and intimate friends. I doubt not, in many cases, this delusive impression may be strong enough, in an applicant for life-insurance, to prompt him in good faith to ignore the existence of a habit of drinking, or the least bearing in that direction.

The question recurs, by what means can the use of intoxicating liquor in a person seeking insurance on his life, be detected by a medical examiner? In an early period of the habit, save in those cases in which the slightest indulgence produces immediate sickness, and at the time of such sickness, it is impossible, by any known signs, to recognize the inebriate tendency of an individual. The formation of the habit does not involve the functions of the body in such a manner, or to such a degree, as to render them inharmonious or disturbing. At a more advanced grade of alcohol experience, when the use of spirits is not suspected in an individual, he may be conscious at times of certain gastric symptoms, insomnia or unusual muscular agitation. He fails to associate any or all of these symptoms with their actual cause, and applies to his physician for advice, or informs a medical examiner of their existence, as he would communicate the fact of occasional neuralgia or transient dizziness in his head. The diagnosis of inebriety is not established, and in the average manner of conducting medical examinations in life insurance; it is not surprising that its distinguishing features should be overlooked. An applicant for a policy of insurance commonly makes an unwilling confession to a medical officer, in language as brief and pointed as is consistent with furnishing proper replies to the questions propounded. He is not disposed to dwell at length on his personal history or to make much of his physical peculiarities. He stands in the light of a witness submitting to a cross-examination, and is careful to communicate only on the subjects to which his attention is directed. The convenient words *yes* and *no*, suggested in advance, perhaps, by an agent, while they are technically answers to questions, at the same time serve as means to withhold from the inquiry much information that should be furnished for a full understanding of the case. It is clearly the duty of examiners to trace out the significance of such marked and prominent symptoms as are revealed in the inspection of each case.

The occurrence of so-called indigestion may imply much or little, according to the manner in which it is

interpreted. It may prove disease in itself, or functional disturbance, or a connecting link between a sympathizing organ and remote structural alteration. Painstaking investigation will rarely fail to disclose the true character of indigestion in a given case, provided opportunity is afforded to follow up the advantages suggested by the grouping of specific details, as they may be willingly or unwillingly obtained from an applicant. The precise nature of loss of sleep, or of muscular agitation, can be as readily ascertained.

It should be kept in mind, however, that the scope of medical examination in life insurance, is not as broad and comprehensive as the investigation of disease in ordinary practice. The applicant for insurance appears before the physician, fearful that some hidden disease may be brought to light, which he knows or does not know to have existence, or he approaches the scrutiny with an air of defiance, as if delivering a challenge to make the most of his physical condition. It has doubtless occurred in the practice of all examiners to discover evidence of disease of the heart, which the applicant would gladly have concealed. As little sensibility characterizes the discovery of such a fraud as is displayed by horsedealers when some imperfection is revealed in an animal, which at the time of sale was pronounced sound and reliable. An impression prevails, in a certain class of minds, that it is the duty of life insurance companies to ascertain the existence of disease, without prompting or assistance on the part of an applicant. This view is not confined to the ignorant alone. It is prompted by a sense of moral obliquity, which is ever quick to take advantage of any weak or equivocal feature in a contract, which would use the railway pass of a friend, and conveniently assume his name, and which, possessed of a habit of drinking, and aware of its consequences, would effect insurance on a life, which might be cut short through its gratification.

The advanced degrees of drunkenness imprint upon the mind and body such evidence of degeneracy, that the habit is at once betrayed in the form of recognizable disease. The life of a drunkard is not, under any circumstances, incurable. We are aware, nevertheless, that drunken lives are not unfrequently insured through concealment of the habit, a loose manner of examination or misinterpretation of symptoms which denote the inebriate condition. If the causative agency of drunkenness is not perceived in Bright's disease, enlargement of the liver, hydro-peritonium, fatty liver, epilepsy, muscular tumor, gastritis, pyrosis, various dyspeptic disorders, decay of the generative function and mental decline, narrated in Flint's Practice as symptoms of alcoholism, the result is the same to a life insurance company if an applicant is rejected because of one or more of the subjective affections mentioned without tracing their dependence upon a remote, exciting cause. The fact, however, should be prominently set forth, that the consequences of inebriety in the production of disease are certain, widespread and oftentimes irremediable.

To the group of symptoms given by Dr. Flint should be added the "pains of alcoholism," so clearly described by the late Dr. Anstie, in his work on Neuralgia, and the following list, furnished in a lecture delivered by Dr. Wm. A. Hammond, before the New York Neurological Society, May 4, 1874. Dr. Hammond says:

"We are now prepared for the long list of diseases and disorders of the nervous system produced by the excessive use of alcohol. The catalogue is made up from my note-books, and is based on cases occurring in my private and hospital practice:

"OF THE BRAIN.

- "Cerebral congestion.
- "Cerebral hemorrhage with its consequences, apoplexy and paralysis.
- "Meningeal hemorrhage.
- "Cerebral thrombosis.
- "Softening of the brain.
- "Aphasia.
- "Acute cerebral meningitis.
- "Chronic cerebral meningitis.
- "Abscess of the brain.
- "Multiple cerebral sclerosis, one of those diseases of which tremor is a characteristic symptom.
- "Every variety of insanity, including general paralysis.

"OF THE SPINAL CORD.

- "Spinal congestion.
- "Antero-lateral spinal sclerosis.
- "Postero-spinal sclerosis (Locomotor ataxia).

"CEREBRO-SPINAL DISEASES.

- "Epilepsy.
- "Chorea.
- "Multiple cerebro-spinal sclerosis, another of those affections characterized by tremor.
- "Athetosis, a remarkable disease which I was the first to describe, and which is now well recognized both in this country and in Europe. The case on which my description was based was one in which the patient was in the habit of drinking sixty glasses of gin daily.

"OF THE NERVES.

- "Anesthesia.
- "Paralysis agitans.
- "Neuralgia in all situations.
- "Neuritis.
- "Neuro-sclerosis.
- "It will be noticed that sclerosis or hardening is a condition of all parts of the nervous system which alcohol probably often produces. It is doubtless the result of the direct action of alcohol on the nervous tissue.
- "In addition to being the exciting cause of many diseases of the nervous system, alcohol probably predisposes to various others in which no direct relation can be traced. Neither does its action stop here, for the descendants of persons addicted to the excessive use of alcohol are liable to various disorders of the nervous system, and there is some evidence to show that offspring generated during a fit of intoxication of either parent are often born idiotic."

MEDICAL SUPERVISION,

IN

DISTINCTION FROM MEDICAL SELECTION IN LIFE INSURANCE.*

By MOREAU MORRIS, M.D.

REPORT.

It is an axiom that careful medical selection is one of the main elements of successful life insurance business.

But, although admitting its truth, it must be said, that, as the term "medical selection" is usually understood and applied by life insurance companies, it falls far short of fulfilling the conditions and accomplish-

ing the results naturally expected from what is supposed to be its searching exactness, and is, comparatively, of but little real value.

This is by no means the fault of medical examiners, than whom there probably do not exist more careful, conscientious, painstaking men in any profession or walk of life.

But the great defect lies in the system or method of securing such information as is necessary to form the basis of a proper medical selection, and thereby to judge of the character of the risk.

The question of how to secure the best and most careful medical selection, has long been and still is apparently one of the most difficult to solve. It is the perplexing problem with nearly every life insurance company at the present day, and well it may be, in view of the rapidly increasing mortality rates in many of the older companies, and in the younger ones also—of the old plan.

As fond parents view with increasing alarm the rapid decease of child after child of their household from some mysterious fatal disease, they naturally look about for superior medical skill to stay, if possible, the effects of the pestilence. Experienced and wise doctors are summoned to the bedside, and with grave, thoughtful countenances, they shake their heads and say, too late! too late! The disease has sown its seed, its ravages are telling with fatal effect; we cannot suggest better remedies, and unless transfusion of new blood may possibly save, death remains only a question of time.

The question of proper medical selection is indeed one of great significance; it is the corner-stone of the edifice of life insurance; its proper position in that edifice should be well considered; its texture and strength well tested and understood; and when once firmly fixed upon a well-grounded foundation it will remain sound and able to sustain the superstructure, of which it forms so important a part.

But with all due deference to experience, whose teachings often fail to be appreciated, it seems to be a patent fact that the solution of this problem must be sought for in other directions, than simply by a change of men, or by more exacting medical qualifications.

No physical exploration can estimate an applicant's probable life expectation; no medical skill nor experience in detecting present disease or impairment can determine the presence of subtle inherited tendencies to disease that may have remained dormant through several generations, but which only await certain unknown influences to become developed in the applicant. True, as a detective discovers a trace of the culprit by some slight clue, so the medical examiner may detect that which has been concealed or unwittingly omitted in an applicant's preliminary statement, and thereby, perchance, save the company from a loss.

Hitherto, so far as ascertained, with one single exception, notwithstanding the acknowledged indispensability of competent medical aid, the medical department of life insurance has held only a position of secondary importance in the business. Common sense would seem to dictate that a business which depends for its success so directly upon a proper estimate of life's expectation in every instance, should have within its executive department medical skill equal, if not superior, to that in its actuarial or financial branches, and such as only *special* medical knowledge and training can afford. It may not be that every medical man is competent for the business; for as in every other business or profession, there needs to be some special adaptation of person and knowledge in order

* An extract from a quarterly report to the directors of a life insurance company.

to diagnose, classify and adjust the integral parts that control life's probabilities.

The laws of inheritance, as it regards health and disease, long and short life, etc., need to be well understood, closely studied, compared and applied. The elements of longevity, as well as of vitality, must necessarily enter into such accounts, and all the forces and influences that control and affect life and health must be considered and well weighed in the problem of estimating the probable life expectation in any given instance.

Human life is subject to so many contingencies; its continuance depends upon so many factors, which only expert medical knowledge can determine, and which cannot be determined by actuarial science, that, so long as the business depends, as it largely does at the present day, upon such uncertainties as are actuarial estimates, based upon general average mortality statistics, there need be no wonder that it cannot be conducted with permanent safety and success.

The application of special medical supervision is the only true safeguard. By it only can the estimation of the probable viability of individual risks be properly and safely given.

If all mankind indiscriminately could be insured, then might the calculation by average mortality risks be approximately correct, and assurance guaranteed by a company, even though with great *inequity* to the naturally long-lived; but as only a small proportion ever become insured, the risk is increased a thousand-fold by this erroneous basis.

Next to the fundamental error of conducting this business upon the "general average plan," has been that of keeping its medical department in a subordinate position. That profession has not failed to recognize its true position, but the greed of speculation has so far succeeded in keeping it quiet. As a class, medical men are not practical business managers; their life studies lead them to shun the more busy marts, to hold out the helping hand, to succor the weak, to protect the infirm, to sustain the depressed and desponding, and they are ever pushed to the wall when they come in contact with keen, sharp, unscrupulous speculation. But as he who lords it over his fellows in competitive business pursuits, or in the wild excitement of stock gambling, will certainly some day beseechingly call for his more humble and long-suffering medical adviser for help from the effects of an overtaxed physical organization, so even now does the business of life insurance call upon its best friend for aid and counsel in its trembling, threatened apoplectic condition.

That the medical department needs to be reorganized there is no question. But its reorganization will avail nothing, comparatively, so long as the present methods of computing premiums and insuring lives upon the "general average" plan is persisted in. There must be a radical change in this respect or no equitable premium rate can be fixed.

Every means should be diligently sought and applied in the conduct of the business that truth, honor, and equity demand, and when they are discovered and have been proved, 'twere worse than robbery to neglect their use.

In the first place, in every well organized company there should be a responsible, specially prepared, medical superior, holding equal authority and responsibility with any other of the executive officers. Upon his and their judgment should the proper premium rate be fixed upon each individual applicant according as *his own* individual characteristics may indicate *his* life's

expectation; *his* vitality and longevity, to wit, *his* viability.

But, it may be asked, how is this single fact to be arrived at, as men differ so much in kind and quality? Certainly not by any general average of thousands upon thousands of the same age; but by a close analysis of all the facts and factors that pertain to this individual. There is the ancestral record; by it may be judged the average mortality age of his individual kind. He has inherited certain life processes which fix a term to his existence; he cannot live beyond them, he may shorten them. If he has done it, how and by what means? By dissipation, contracting incurable disease, overtaking his vital energies, dwelling in insalubrious districts, violating good sanitary laws, recklessness, useless exposure, or accident? Each and all of these elements of impairment must be weighed and judged as to their relative or combined influence in shortening the natural life term of the applicant under observation.

The preliminary step, then, should be to ascertain as far as it is possible from the ancestral family record of each person the ages of his living relatives, the ages of all who have died, and of what diseases they died. This record should include the grand-parents always, and as many of the great grand-parents as any record can show. It is important also that these statistics should be clearly obtained on both paternal and maternal branches—such as uncles and aunts, brothers and sisters—giving their ages and conditions of health if living; if dead, age at death and cause of decease. So much of the details of the physical characteristics of each of those persons as it may be possible to get should also be recorded.

We have now presented before us a series of lives through which and with which this one has many characteristics in common; he is after, and one of, that kind. Whatever of life is inheritable is here shown; whatever of inheritable disease he may or will have, if there has been any, will almost certainly appear somewhere in this record; and if there has been none, have we not the fact almost indubitably established that in him there will be none; therefore there is very, very little risk in that direction.

The next question in order is, naturally, the special constitutional characteristics of the individual, whereby we may judge from which branch of the parental house he inherits his strongest viability peculiarities, etc. These, in detail, include height, weight, equipoise, and both a general and minute descriptive picture of his outer person.

Habits, vocation, residence, intelligence, past and present health, and other incidental facts, such as army exposure, various residences that he may have had and their local diseases; injuries, whether permanent or trivial, etc., the details of which for want of time are here omitted.

To all these details which fully illustrate to a critical eye the life picture, as well as the inherent tendencies, are added a general description of the person, giving his biometrical measures of the head, trunk, limbs, all of which form a complete record of the party. One accustomed to the analysis and synthesis of these elements of viability can readily form a very accurate judgment as to the probability of any person's life expectation.

In view of these considerations, no right minded and true man can dispute the fact, which his own intuition teaches him, that he has within himself potentialities, governed by certain fixed laws, which give a period to his existence; that in some it is naturally shorter and in others naturally longer than the

general average of all mankind. True, this vital principle governing his longevity may be so interfered with as to deprive him of its full influence, or the accidents of life may suddenly cut it short. The laws of longevity being fixed, it is not a difficult matter, by the proper application of those laws, to estimate very closely the probable natural life expectation of any individual.

The facts to which we here refer show that there is something behind and beyond the present physical condition which governs and regulates the viability, and which must be sought for in other directions than by listening to the heart and lungs, feeling the pulse, taking the measurements of the height, ascertaining the weight of the body, etc. Men have inherited vitalities and diseases which are constitutional; have habits which affect, vocations which modify, residences which promote or destroy health; they may be robust or feeble; they have idiosyncrasies inherited or not, instincts and intuitions, all of which are indicated by signs and manifestations hung out upon the outer wall for our reading.

The further problem then becomes reduced to the amount of impairment that may have supervened upon the proposed life, the effect of habits, or the accidental danger to which it may be subjected.

It is the perfection of detail following the true principles of life-governing circumstances, that alone can produce signal success in this business. It is the application of the principles of biometry with reference to natural longevity, and of those of medical science with reference to unnatural impairments, and of the experience of statistical facts to life's accidents, by the medical expert, that constitutes the working plan of all true life insurance, in the estimation of risks.

The following practical illustrations will perhaps more clearly exhibit the true value and status of expert medical supervision, in estimating the probable life expectation by which to fix a premium rate in any given case submitted for insurance.

In order not to confuse the mind with details, it will be perhaps sufficient that two extremes, exhibiting types of the best and the poorest cases insurable in ordinary average premium companies, should be used. Between these there exist every grade whose premium rate needs to be adjusted in accordance with the expectation of the person, and which cannot—in justice either to the company, its policy-holders, or the applicant—be adjusted by any general average table.

"Like begets like," and to calculate that the longevity of a class of men will be greater than the average of its ancestors is erroneous and unsafe. Persons descended from short-lived ancestry cannot beget long-lived children, and persons descended from long-lived healthy ancestors are unquestionably entitled to the benefits of this ancestral inheritance which—if not impaired by disease, physical defect, or excesses—most assuredly should place them in the superior grades, and entitle them to the lowest premiums.

F. D. S.—Age 33—Married.

Ancestral record:

Paternal—Grandfather died at 90, old age; grandmother died at 92, old age. Maternal—Grandfather died at 85, old age; grandmother died at 80, old age. Father living at 73. Mother living at 70. Paternal—Uncles, 3, all living, aged 62 to 70. Aunts, 1, dead; age, don't know. Maternal—Uncles, 3, living, aged 60 to 70; aunts, 2, living, aged 60 to 66. Brothers, none. Sisters, 4 living, aged 33 to 40. American.

White. Good proportions. Compact. Height, 5 ft. 9 in. Weight, 175 lbs. *Head*, large, measures 5½ in. through temporal fossae; 5 in. from nasofrontal articulation to orifice of ear. *Nose*, large, long, expanded nostrils. *Lips*, long, red. *Trunk*, large, long, measures 25 in. *Shoulders*, square. *Chest*, expansion 3 in., well developed, round, long. *Abdomen*, medium round; girth, 35 in. *Hips*, broad. *Back*, straight. *Limbs*, medium size; muscles, hard. *Hair*, brown, abundant, coarse. *Beard*, lighter, coarser. *Eyes*, hazel, straight. *Complexion*, dark, clear. *Features*, large, regular. *Teeth*, sound. *Neck*, medium. Has had diseases incident to childhood only. Vaccinated well. Vocation, farmer. Born and always lived in Maine. *Habits*, correct and temperate, and always been so; never drank any distilled or fermented liquors; is a free liver; bathes weekly; gives attention to ventilation, especially of sleeping room; rises and retires regularly, early; meals, regular; uses tea and coffee; never uses tobacco in any form. Health is now perfect.

Again.— J. J. A.—Age 21—Unmarried.

Presenting nearly the same personal characteristics as F. D. S., except height 5 ft. 10½ in., weight 163 lbs., having same head measurements, length and size of trunk, and in perfect health, gives the following

Ancestral record:

Great grandparents were all of them over 90 years of age at death. Paternal—Grandfather living now, aged 70; grandmother living now, aged 70. Maternal—Grandfather living now, aged 74; father living, age 47; grandmother living now, aged 74; mother living, age 47. No uncles or aunts on paternal side. Maternal—Uncles, 6, all living, ages from 25 to 47; aunts, 1 living, age 38. Brothers—2, aged 12, 21. Sisters—1, aged 23.

In this case it may be observed there has not been a death in the three generations since the great great grandparents, all of whom were over 90 years of age at death; and in the first instance given it will also be noted that there was but one death since the grandparents, none of whom died under 80 years of age.

In view of such records is it not a violation of common sense, and all sense of justice, to charge a premium to either one of these parties upon the basis of the average duration of all human life? viz., at their actual age. Are they not entitled to a rebate on account of superior longevity, habits, physique, health? Most unquestionably. We will now present another illustration.

F. E. P.—Age 24—Married.

Ancestral record:

Parental—Grandfather died 83, gravel; grandmother died 50, tumor. Maternal—Grandfather living, 73, health good; grandmother living, 70, health good. Father living, 52; mother living, 48. Paternal—Uncles, 4 living, 38 to 65; 2 dead, 3, 55. Aunts, 1 living, 40; 4 dead, 28 to 60. Maternal—Uncles, 3 living, 35 to 40; 1 dead, 20, fits; aunts, 3 living, 28 to 40. Brothers—4 living, 11 to 19. Sisters—1 living, 9; 1 dead, 11, dropsy. American. Height 5 ft. 6 in. Weight 134 lbs. *Head* measures 5½ in., 4½ in. *Nose*, medium. *Lips*, long, red. *Trunk*, medium long, measures 24 in. *Shoulders*, square. *Chest*, well developed, expansion 3 in. *Abdomen*, medium round; girth, 32 in. *Hips*, medium. *Back*, straight. *Limbs*, medium; muscles, hard. *Hair*, brown, curly. *Beard*, lighter, finer. *Eyes*, hazel, straight. *Complexion*,

dark, clear. *Features*, medium, regular. *Teeth*, so md. Has had other diseases besides those of childhood. Vaccinated well. *Vocation*, meat market. Born in Maine, always lived there. *Habits*, correct and temperate; uses ale, has been intoxicated seldom, two years ago; attends to ventilation of sleeping room; rises and retires early; active; uses tea and coffee, weak; no tobacco in any form. *Health*, good; had some rush of blood to head years ago, none for three years; some kinds of food produce inconvenience, fresh fish; has piles, bilious colic once or twice a year; has chronic rheumatism at times; otherwise in good health.

We have here an example of fair ancestry, but with some constitutional impairment which crops out in his statements with regard to his own condition of health. In the account as posted up against him we find questionable points against ancestry, constitution, habits, vocation, health. These indicate the impairments natural and acquired, and all without a medical examination.

Is it necessary to go farther? Cannot a medical or even a non-medical supervision decide with pretty accurate judgment that the risk in this case is almost dollar for dollar.

Other, though dissimilar cases, showing specially the tendency of ancestral inheritance.

E. C. G.—Age 34—Married.

Ancestral record:

Paternal—Grandfather died 80, old age; grandmother died 43, stoppage. Maternal—Grandfather died 50, consumption; grandmother died, don't know age or cause; father living, 65, in good health; mother dead, 45, stoppage. Paternal—Uncles, 4 living, 41 to 63; aunts, 2 living, 60 and 30. Maternal—Uncles, 1 living, 55; 3 dead, 38—at sea, 50—consumption, 60—don't know cause; aunts, 1 living, 55; 2 dead, 45—consumption, 35—result of a cold; brothers, 2 living, 38; 2 dead, 14—hip disease, 6 months—don't know; sisters, 1 dead, 21—consumption; 6 living, 28 to 50. American. Height, 5 ft. 11½ in. Weight, 175 lbs. *Head*, measures 5½, 5. *Nose*, medium. *Lips*, middling long, thick, red. *Trunk*; medium long, measures 24½. *Shoulders*, sloping. *Chest*, medium; expansion 3 in. *Abdomen*, medium broad; girth, 35½. *Hips*, medium. *Back*, straight. *Hair*, Saxon, light, middling fine. *Beard*, darker. *Eyes*, light blue, straight. *Complexion*, fair, clear. *Features*, medium, regular. *Teeth*, sound. Has had fever and ague. Served in army four years. *Vocation*, brickmaker. *Habits*, correct and temperate; uses tea and coffee; smokes. *Health*, good.

W. W. R.—age 25—Married.

Ancestral record.

Paternal—Grandfather died at 70, don't know cause; grandmother died at 70, don't know cause. Maternal—Grandfather died at 80, old age; grandmother died at 40, consumption; father died at 58, liver complaint; mother living at 60. Paternal—Uncles, 4 living, aged 50 to 60; 2 dead, 60—liver complaint, 60—don't know cause; aunts, none. Maternal—Uncles, 1 dead, aged 45, fatty degeneration of heart; aunts, 1 living, aged 70; 3 dead, consumption, aged 39 each; brothers, 3 living, 24 to 40. Sisters, 2 living, 24, 30; 1 dead (infant). American. Height 5 ft. 8 in. Weight, 140 lbs. *Head* measures 5½ in., 4½ in. *Nose*, medium. *Lips*, short, red. *Teeth*, good. *Trunk*, long, 25½ in.; measures 37½ in.; expansion 3½ in. *Chest*, well developed, broad. *Abdomen*, 32 in. *Back*, straight. *Muscles*, hard. *Fingers*, well webbed. *Foot*,

arched. *Nails*, slightly incurvated. *Hair*, brown, fine, abundant. *Beard*, lighter. *Eyes*, light blue. *Complexion*, fair. *Diseases*, incidental to childhood only. *Habits*, correct, temperate, uses no spirits nor tobacco. *Vocation*, manufacturer of furniture. *Born*, and always lived in Maine. Insured in two life companies.

Remark by Medical Examiner:—This man has a splendid chest development, and no present indication of pulmonary diathesis.

These two instances exhibit so great a tendency to inheritable or transmissible disease, as appears from the ancestral record, that it would be entirely unsafe for any company to insure them at actual age, and therefore they should be charged a premium in accordance with the unusual risk as estimated by the probably short expectation of life in each case. Yet one of them says he is insured in two life companies. Good for him, but bad for the companies.

It must not be understood that the ancestral record by itself is to be considered as the essential element in estimating a person's life expectation. It simply exhibits the potential inheritable vitality. It may or may not have descended to the proponent. But it is one of the factors by which the individual constitutional characteristics are to be elucidated in the further study of the personal characteristics of the individual's constitution.

The complete study of an individual's viability, or probable length of life, requires a further consideration.

Whether he has really inherited those constitutional characteristics inferrible from his ancestry; whether, if possessed naturally, they have been continued, and whether they probably will be continued in him or not.

To judge of these facts requires a complete knowledge of his personal peculiarities, his habits, vocation, residence, intelligence, instincts, past and present health, all of which must be particularly described to form a complete basis for a proper estimation of his own personal longevity.

In the foregoing I have considered only those conditions antecedent to and independent of the medical examination proper. This examination presents, when carefully filled out upon a proper blank, an almost complete medical and physiological history of the applicant; it also affords an independent statement of facts, with which the interested statements of the applicant may be compared, and any error, intentional misrepresentation or falsification at once detected.

This blank may be filled up by any respectable physician, and, when considered in connection with all other information afforded by the applicant, and by his family physician's and friend's certificates properly filled out, places in the hands of the chief medical officer such a combination of facts in regard to the party's life history, his antecedent inheritance respecting longevity and disease, etc., as afford an almost unerring basis upon which to form a judgment as to the true character of the proposed risk.

What I wish to explain more particularly is that the applicant's blank, carefully filled out in proper form, is quite as necessary, and, in fact, even more useful, than the medical examiner's blank filled out by him.

They are both pre-requisite to a perfect understanding of an applicant's viability, and the proper rating of the risk; but it is in the applicant's blank, rather than the medical, as usually found, that the greatest improvement is needed.

Indeed the present medical blank of most of the companies would do very well for its purpose, but the

applicant's blank, as we usually see it, is very deficient in many important particulars.

The medical blank should be intended as only correlative to the applicant's blank, as indeed it must be. It can afford only such additional "expert" knowledge of facts and conditions as an applicant might overlook or be ignorant of, in regard to his physical or pathological characteristics.

The chief prognostics of the viability of the healthy person must be found and can be found only in his own part of this application. The description of his ancestry and of himself to a great extent can only be furnished by him if it reaches the company through the medical blank; it is a repetition of some of the facts in his blank for the purpose of comparison at the home office, while it should be fully and in every possible way impressed upon the applicant that he must be honest in his statements and replies, and in good faith answer all the questions put.

It is found in practical experience that the medical blank is corrected by the suggestions of the applicant's blank quite as often, nay oftener, than the latter is corrected by any information gained from the former. It is also found better, as a rule, to have all that can be stated by the applicant put down by him on his blank, thus fixing the responsibility for good faith upon him as far as possible; and this also saves the time of the medical examiner. Indeed, if the applicant's blank is properly drawn and filled out, giving all the details that the applicant can give about himself, it is seldom that anything can be added by the medical examiner in that respect.

MEDICAL SELECTIONS.

In discussing questions involving the healthy progress and ultimate safety of the life insurance business, we are often called upon to deal with subjects in themselves regarded as distinct and separate from each other. But when applied to the business, they become inseparably connected—an unbroken chain, without which cause and effect would have no binding links. We must have safe investments, a safe rate of interest, a safe standard of mortality, and a safe standard of health. None of these can be neglected, and the desired object be attained. Nor is any one more important than a safe standard of health, or what is usually called safe, or sound risks.

To keep these risks up to this standard is the professed object of medical selections. Perhaps there is no point of danger to which companies are more liable to be exposed than this. The character of securities may be ascertained from disinterested parties, the rate of interest may be determined by outside considerations; the rate of mortality by past experience, and the standard of health by the exercises of sound judgment. Here there is no one to conceal facts which no one else knows. But in medical selections the case is different. The applicant for insurance may have disease within him which no medical skill can detect. He may be aware of this fact and use it to the disadvantage of the company and to the injury of all its members. That this has been done in many instances no one can doubt, and that it will continue to be done in the future there is reason to fear.

If all such cases could be understood when application for insurance was made and an extra charge equal to the extra risk was assessed, no one would suffer; the extra charges would be equal to the extra losses. But as this cannot be done in all cases nothing but

the greatest care in medical selection is left for a company to depend upon. That such care is not always exercised seems to be evident from the high rate of mortality lately experienced by some companies; or if it has been, they have experienced fluctuations in the rate of mortality amongst sound lives, such as would render all former assumptions and calculations worthless. But the correctness of these assumptions and calculations has been too well established to admit this conclusion. These remarks have the greater force when we remember the average duration of life policies, unless there is a great disparity between the number of sound and unsound risks whose insurance is forfeited. That there is any disparity is yet a mooted question.

But let us look at the advantages of medical selection. What is their magnitude? How far down the history of companies do they reach, or at what point do they vanish? These are questions which have attracted considerable attention and some discussion. But not till recently have we come into possession of facts which lead to any thing much better than mere conjectures. And however near the truth these conjectures may have been, they needed confirmation, such as actual experience furnishes before they could be received as trustworthy by prudent men.

In the year 1869, the Institute of Actuaries published the mortality experience of twenty life companies doing business in England and Scotland. In that experience, the advantages of medical selections end with the fifth year after insurance is made. Here the number of risks upon which observations were made is quite large enough to give reliable results, and we might accept them as being entirely trustworthy in the absence of additional facts. But fortunately, we are put in possession of other facts which show that the conclusions reached by the Institute of Actuaries were well founded.

These facts are found in the late report on the Mortality Experience of the Mutual Benefit Life Insurance Company of New Jersey in Table No. IV., and chart marked B. This report shows that the advantages of medical selection are about the same in this as in other countries. We have already referred to this matter in our former review of this valuable document; but the information it furnishes on our present subject is so clear and satisfactory that we take the liberty of alluding to it once more.

In the chart referred to, it will be seen by the dark zig-zag line which represents the company's actual experience, that it halts upon the upright line on the left, a little above the horizontal line marked 60. A similar line at the top marked 100, represents the American experience. Here then the advantage of medical examination for the first year is about 38 per cent. of the American Experience. In the second year, this same line falls upon the second upright line at the point marked 70, consequently the advantage is 30 per cent. of the American Experience, and so on to the end of the fifth year. In the sixth year it passes above the red line in the chart, which marks the average mortality experienced by the company.

Now turn to Table No. IV., and we see that the average mortality for the first five years, after insuring, is .786 of the American Experience; but the average mortality for the whole 28 years of the company's experience is .862 of the American Experience. The difference between .862 and .786 is .076. But the average mortality in the 23 years which follows the first five years is .946 + of the American Experience. Now subtracting from this rate for 23 years (.346 +) the average rate (.786) for the first five years, we have .160.

This .160 is the mathematical expression for the advantages of medical selection according to the experience in the above report.

If we are correct in these calculations, assuming that the calculations in the report are correct, the advantage of medical selection is about 17 per cent. of the mortality experienced after the effects of selection disappear. We are now speaking of the advantages in regard to the number of deaths. Of course, the amount of death claims will be formidable in proportion to the number of deaths, not, however, without slight deviations, the same in extent as in the years which follow.

The advantages we have found are to a life company something like a man getting a good start on his day's journey. He travels throughout the day with less anxiety and annoyances than if he had made a bad start. A good start may compensate for hindrances on the way. And so it is with life companies. They will find that a good start with new risks secures advantages which they can ill afford to neglect. The journey is too long to start with bad freight, or that of an indifferent quality. It must be good, or the tariff must be raised.

Our object at present is not to advance new arguments in favor of medical selection; but to enforce such as have often been presented to the public. The arguments repeatedly made are so forcible—accumulating facts bearing upon the subject are so numerous and weighty—that they need only be kept before the public to secure what is needed. Those who have the care of this branch of the business—under whose medical skill the applicant for insurance must pass before policies of insurance are issued—must feel the responsibility which rests upon them. They must feel that to a certain extent the success of a life company is in their hands, and the protection of widows and orphan children is safe or in jeopardy by their fidelity in the discharge of their duties.—*The Spectator*.

Miscellaneous.

HERBERT SPENCER'S THEORY OF MARRIED LONGEVITY.—In his recently published *Study of Sociology*, Herbert Spencer assails a theory that has long been current in life insurance. That married life is favorable to longevity has generally been regarded as satisfactorily proved by the numerous statistics showing, almost without exception, a greater longevity on the part of the married. When the ratio of deaths in the two classes stand as ten to four and even twenty to four, there would appear to be little room for doubt. But to this astute social scientist the evidence, strong as it seems, furnishes no warrant for the current belief. He regards the case as a substitution of cause for effect. In other words, greater longevity is not the consequence of marriage; on the contrary, marriages are clearly traceable to influences favoring longevity. The principles of natural selection work so strongly in deciding between the benedicts and the bachelors, that the long lives are drawn to the former and short lives to the latter.

Marriage, he holds, is regulated by ability to meet its responsibilities. The qualities which give the advantage here are intellectual and bodily vigor, prudence, and self-control; these, too, are the qualities which determine a prolonged life or a premature death. An even more direct relation is to be found in the

instincts which lead most strongly to marriage. The reproductive instincts and emotions are strong in proportion as the surplus vital energy is great, and this in turn implies an organization likely to last. "So that, in fact, the superiority of physique, which is accompanied by strength of the instincts and emotions causing marriage, is a superiority of physique also conducive to longevity." Another influence tells in the same direction. Marriage is determined by the preference of women as well as the desires of men, and other things being equal, women are attracted towards men of physical and intellectual power, refusing the malformed, diseased, and ill-developed types.

In the operation of these three elements Mr. Spencer finds all that is needed to account for the striking difference of longevity between the classes, and declares that "the figures given afford no proof that marriage and longevity are cause and consequence; but they simply verify the inference which might be drawn *à priori*, that marriage and longevity are concomitant results of the same cause."

It is impossible to deny the principle of natural selection here laid down by Mr. Spencer, a powerful influence on the relative longevity of the classes, and if either theory must be accepted to the exclusion of the other, this one may perhaps have the better title. Every person conversant with sociological facts knows that these selective forces do exist and operate with vigor, while the statistics themselves furnish the strongest evidence of advantages resulting from a married life. But it is more reasonable to suppose that the truth lies between the two, and that in carrying out the legitimate functions and satisfying the natural instincts of life the effect reacts upon the cause, and influences favorable to longevity are intensified in their action. The disparity which exists between the relative mortality at different ages, and the greater diversity during the period when marriage may be supposed to exert its strongest influence, certainly favors this view.

The question itself is an important one in its bearings on the statistics of other classes as well as this one. Like differences are shown to accompany occupation, social standing, and residence in foreign climes. It is important to know how far these differences are attributable to the circumstances, and how far the conditions of life may be due to personal differences more or less favorable to longevity. It is certainly true that the intellectually strong gravitate towards a professional career with its attendant length of life, that the physically sturdy and intellectually unimpassioned gravitate to the farm, that the moral and self-denying seek the ministry, and the nervous and excitable characters find their congenial home in the bustling and hotly contested walks of life.

A judgment of the individual, based on his employment or position, must be modified to meet the circumstances that have placed him there. Southern climes have been the favorite resort of invalids suffering from pulmonary complaints, and the statistics of a southern residence would naturally be unfavorable, but they would not apply with equal force to a sojourn for business or pleasure. The law of its life applies equally to a class as a whole, whether the classification is due to the law or the law to the classification. But if, as in life insurance, the unsound lives are first weeded out, the influence of the law is limited to its causal relation, and the inquiry as to whether Mr. Spence's cart is before the horse, or the horse before the cart, has no considerable practical importance.—*Insurance Monitor*.

Original Communications.

SOME REMARKS ON DIPHTHERIA.

By EZRA M. HUNT, M.D.,

METUCHEN, NEW JERSEY.

RECENT experience as to diphtheria, and the mortality to which it has attained during more than a year of epidemic prevalence in New York City, may well excite our profession to increased thoroughness in the study of it. Each disease has its science, and the science of any one disease means the accurate classification of its facts by accurate observers, and the deduction therefrom of correct principles of treatment. What we are most needing in diphtheria is that every observer should give us accurate, truthful clinical observation, and then that such as are most competent should collate, test, and arrange the facts so as to give us deductions founded thereupon. In this article all we propose to do is the former, and then to add a few thoughts on the various hypotheses of diphtheria.

I have met the disease, through a period of years, in four epidemics, have twice had it in my own family, and while not having the multiplicity of cases seen in a public institution, have been able to study it in the distinct localities of a village and country district. To detail the varying phenomena of each case, or of each epidemic, would take a volume rather than an essay. I can only give such generalization as is the result of special observation, to aid others in comparing their own experience, and myself to gain knowledge by such comparison. I saw my first defined case of diphtheria in——. It was a young lady of eighteen, whom the family had treated for tonsillitis. I found her with the membrane over the entire fauces, with parotid gland greatly swollen, and with a failing pulse. She had not yet taken to her bed, but did that night, and died in about thirty-six hours. There were three in family, and she was the only young person. A few days after, one of the other members had a diphtheritic deposit on one tonsil, which I saw at its beginning, and cauterized, and there was but little subsequent trouble. A week after, a young man, also the only young person home in a family of three, had a swollen throat for four days, went to bed earlier than usual one night and died at three o'clock the next morning. Although not seen by any physician, a careful history satisfied me of its identity with the former case. These, so far as I know, were the first cases in the county, and we refer to them because of this one item. A colored woman fleeing from a family on Staten Island in which three or more children had died of the "throat distemper" prevalent there, came to the house of the first-named patient and spent an hour the next day, combing and crimping her hair for her. After being there a week she made her only other visit to the house of this other person, over a mile distant. Within three weeks both these persons died of diphtheria.

There were no immediate or consecutive cases, but within the next year I had occasion frequently to see the disease in that township, generally losing my first patient whenever called, and the rest recovering. It would break out in families detached from each other and without any known cause. The trouble with first cases was that the family did not recognize it until the neck was much swollen, and then too often the poison had so infiltrated the lymphatic system as to be beyond sufficient dilution or neutralization. Now and

then such a case recovered, but this was the exception. It has happened to me only in five or six instances to lose cases treated from the outset. A second epidemic, not so extensive, but equally severe, occurred four years later. Now and then a parent was attacked, and in the case of one mother it was a severe struggle, followed by paralysis of throat, which for a time gave nasal tone to the voice, but resulted in a final restoration. The third epidemic was milder in its type.

Of cases occurring just now, the first returned from a visit to New York, had sore throat soon after, and was seen by me one week after first symptoms. The swelling was slighter than usual; the diphtheritic membrane not extensive in the throat, but croupous symptoms prominent. The patient probably died from the extension of the disease through the bronchial tubes. The other members of the family were attacked, but only one at all severely. This one early showed the same complication as the first, and I varied treatment by using ipecac and senega, with advantage. The cases we have now are less malignant, and not so inclined to glandular swelling. There is such a prevalent tendency to sore throats as to make it a little difficult to diagnose between the various forms, and very easy for prospecting practitioners to sum up manifold cases. I have seen tonsillitis, with pus discharge, diphtheria, and an "acne"-like condition of tonsil occurring in the same family within ten days of each other. Some of these cases, in which five or six whitish acuminate points form on the reddened tonsil, spread out and run into a genuine diphtheria. How far this form of sore throat is diphtheritic in its start, and bears relation to malignant diphtheria, as scarlatina does to scarlet fever, is a matter needing to be carefully studied.

The first thing to be done with a diphtheritic child is to put it to bed. This helps to isolate it from the other children, and is also important for treatment. The child is often so much inclined to sit up, that the physician needs to be explicit on this point. The short early stage of diphtheria often has an inflammatory type of fever, and it will not do too rapidly to tumble in nutriment, stimulants, and tonics. The bowels, unless relaxed, often need to be unloaded by a mild laxative. As we are to rely much upon good digestion and ready assimilation, it is well to have the *prima via* comfortably clear. Counter-irritation is early indicated. Not such as is destructive, but that by salt-pork rubbed with mustard in the country, or some elegant liniment, such as the colorless iodine liniment when convenient. The neck must not be bound up in three or four thicknesses of flannel, but a single band reaching up over the head, instead of around the neck, is well. If the glands are swollen there should be frequent applications of the liniment, and oil-silk inside the flannel-band.

The throat of course has been carefully examined. Some good doctors have much to learn about the best way of examining the throat of a child. It is not difficult to get a thorough survey by practice, and to teach most children to make a full showing. Let the child protrude the tongue as far as possible, then open the mouth very wide and give a cough or a gasp; after trying two or three times they will succeed, and if not they may then drop the tongue against the teeth, and will more readily submit to a quiet, slow depression of the tongue, not too far back, with a spoon or small spatula. It is well to get a thorough view of all the cavity. If we can see a throat when the diphtheritic deposit is circumscribed, we always prefer to give the deposit and the parts about it a thorough pencilling with nitrate of silver in solution. It is both sedative

and caustic. I am so sure that many a time I have limited the disease thereby, that in this class of cases we cannot dispense with it. I do not like to do it, and have often had my face speckled from the saliva when just finishing, but nevertheless believe in its local value. This is quite different from an advocacy of promiscuous swabbing. We are quite aware that a large number of practitioners are for making light of local treatment, or resort only to tannin and glycerine, and the like. But because this is a constitutional disease, that is no reason for neglect of local measures. Many an ulcer and many a skin disease, although constitutional, calls also for local treatment. Watson and others have, in other forms of throat trouble, recognized the fact that the local secretion is absorbed and reinfects the system. Whatever may be the hypothesis as to the local deposit, whether infusorial, fungoid, or neither, it had better be looked after as a very unhealthy presence. Even frequent rinsing of the mouth, and an avoidance of swallowing often is worthy of attention. I accidentally had a bottle of Squibb's carbolic acid solution (No. 3) frozen, and found the ice of this valuable for occasional local use in the throat. It is easily managed, and often quite grateful to the patient. Several of our remedies are to be regarded as having both local and constitutional effect. In the outstart, when the patient has excessive heat and dryness of skin, a little ipecac may well be combined with the chlorate of potash, and given alternately with the chlorate alone. We believe the chlorate of potash has not only a local but a constitutional effect, although Wood, in his recent *Materia Medica*, denies any constitutional effect from it. It certainly has almost specific local effect in stomatitis. As it goes through the system also in the form of chlorate, so that a part reappears in the urine, we will at least give it a chance for "local effect," if you choose so to call it, all along its course. We like these antiseptic or antizymotic medicines which reappear in part in the secretions, showing that they offer their services all along the line. Chlorate of potash dissolved in the tinct ferri chlorodi is our most uniform remedy after the first day. It should always be held a little in the throat before swallowing, and may also be alternated as a gargle, after a free use of the chlorate of potash at first; five grains in five drops of the best tincture will generally suffice if used every two or three hours. Sulphate of quinine is generally needed throughout the course of the disease, in three-grain or more doses every three or four hours. That we may get both its local and constitutional effect it should be used dissolved in only a little liquid. It is best between meals, and is especially needed from two to seven A.M. We all agree that this is a disease in which nutrition is demanded, but in the general tendency to support, we need constantly to guard ourselves with the fact that all food must be digested and assimilated well for several days to meet our purpose. Too frequent food and too frequent medicines must be limited by this rule. Let three meals be made as usual, and also an extra night meal if required, and all with the better foods. Then let milk or beef-tea, or oyster juice, or milk punch, come in between, if needed, as they are quickly disposed of. We have long felt that beef-tea as a nutriment is overrated and so now say Smith and other good authorities. It is a condiment. Orange juice or cranberry juice taken with the regular meals, probably sharpen digestion. In all supporting treatment, keep the assimilating machinery in working order.

In diphtheria, too much attention cannot be paid to all secretions, to purity of air, to regularity of tem-

perature, to change of bed-clothing, and all hygienic conditions. Success in these zymotic diseases depends very often on attention to incidentals. Dilution is the great law as to all these recondite poisons. Neutralizers, oxidizers and absorbents should be at hand to aid, but are only adjuncts. So chloride of lime, sulphate of iron and dry charcoal are not out of place. When diphtheria appears in a family, it is well besides to have each member cleanse the teeth or mouth two or three times per day with a tooth powder of equal parts of chlorate of potash, powdered gum arabic, and granulated sugar.

In our studies of diphtheria we should always keep a careful eye to its nerve element. In older children we see an unrest often, such as we seldom find except in some form of subdeltus. I saw for ten days a young man whose chief manifestation of the disease was a restless walking to and fro, and who, up to the time of death showed this uneasiness. The vasomotor system is early involved, and heart-paralysis or enfeebling occurs. The ammoniated tincture of valerian ought to be of service in cases of such enfeebling action, but I have not used it enough to express clinical opinion.

In reference to the hypothetical views, now sometimes expressed as to the disease, we must still hold them *sub judice*. The finding of bacteria or fungi with the microscope itself proves but little. One or the other of these is a constant attendant upon all fermentative processes. In manifold diseases either fungi or vibrios, are accidental, or occurrent far more than causative. In fact it would seem that these often afford one of Nature's ways of disposing of putrefactive and distinctive changes, the infusoria or fungus being less injurious than the disease, except under aggravating disturbing circumstances. We have been looking of late into the germ theory (hypothesis) of disease, life, etc., and find ourselves more troubled with the conflicting testimonies of microscopists than with the diphtheria. Not being personally an expert, I can only compare and wait for higher magnifying powers. Dr. Bastian has found that living things can, by molecular combination, originate from non-living materials, and Dr. Meissner says he has "succeeded in directly producing life in inanimate bodies." Those who hold that the atmosphere everywhere is full of fungus germs, and also of those of infusoria, germinating so readily as to appear spontaneous, are apt to see more destructive potency in these than is necessary. Once the animalcules of water were its great dread, but we now find they often do good; and organic matter and some minerals are far worse. We suspect there are other naughty things about diphtheria than microphytes. Archeobiosis and panspermism, homogenesis and heterogenesis must themselves be more defined, and actual results must become surer as causes, effects or incidents, before we can assume that they constitute the morbid animus of the disease. Let us have all this under notice at the same time, remembering the chemistries of disease, the fact of blood-poisons, the insidiousness of the results of animal and vegetable putrefaction in arrested forms, the meaning of absorption of poison as declared by the lymphatic glands, the significance of nerve-impressions and nerve toxics, and all these other points which arise to "advanced thinkers" in medicine, who have not made "germs" a speciality. Most of all, the closest clinical observations and record of facts is needed to aid us in studying this and some other diseases, and it is only as helping a little in this regard that we have written these notes.

The *Sanitary Journal* is the title of a new periodical that appears in Toronto.

THE TREATMENT OF ABORTION.

By ALEX. J. C. SKENE, M.D.,

Professor of Gynecology and Clinical Obstetrics in the Long Island College Hospital, Brooklyn, N. Y.

ABORTION is an occurrence to which every pregnant woman is liable. Though generally the result of accident or conditions over which the woman has little control, it is frequently brought about intentionally by those who wish to avoid having children. The practitioner is constantly being brought into contact with such cases, and as they may be looked upon to some extent as emergencies, I am led to believe that any contribution, however small, to the management of abortion, may be of some interest.

What follows will have reference to premature expulsion of the ovum at any time from the first to the end of the fourth month. The discussion of causes will be purposely omitted from this paper. It would appear on first thought, that a thorough knowledge of the causes of abortion would be necessary, in order properly to comprehend the treatment; but such knowledge applies more directly to the prevention or the removal of the causes of this accident. So far as the simple management of the expulsion of the ovum is concerned, the subject can be fully understood without any special reference to etiology.

It should be clearly understood that abortion often takes place without there being any necessity for interference on the part of the physician. Although an unnatural occurrence, the vital powers are sufficient in some cases to accomplish the work without the aid of medicine or surgery. On the other hand, there are several ways in which danger may arise, which calls for the most active treatment. Indeed, in the great majority of cases the physician is called upon to either guard the patient from danger or relieve suffering.

The point to settle, when a case of this kind comes up for consideration, is the diagnosis. Firstly, is the patient threatened with abortion? Secondly, can it be arrested, or must it go on? To answer the first, it is necessary to make sure that the patient is pregnant, a diagnosis which is not easily made with certainty. All men of experience will acknowledge the difficulty of diagnosing pregnancy in the earlier months, and on this account I hope to be pardoned for deviating from the main topic, in alluding to the signs and symptoms of pregnancy, which are supposed to be perfectly familiar to every one. I refer to this matter for the purpose of calling attention to a classification which I believe has the advantage of being more easily remembered than that given in text books.

First. Symptoms manifested by the general system—PRESUMPTIVE.

Second. Signs and symptoms manifested by the reproductive organs—PROBABLE.

Third. Signs manifested by the fœtus in utero—POSITIVE.

Under the first head may be classed all the constitutional symptoms: sympathetic derangement of the digestive and nervous systems; morning sickness, or nausea and vomiting, eructations, heartburn; craving for particular articles of food and loathing others; constipation, salivation, and various neuralgic pains. Either or all of these may be present or absent. At the same time that the patient may have all these symptoms, the general health appears to be good; that is, nutrition and circulation are normal.

Under the second head are classed all the changes occurring in the pelvic organs and mammary glands: suspension of the catamenia, increase in size of the

uterus, as observed by prolapsus at first and then ascent; fluctuation or elasticity of the uterus; change in color of the mucous membrane of the vagina; changes in the mammary glands.

The third division comprises ballottement, the placental souffle, fetal heart, and fetal motion.

With the best skill and the greatest care, the diagnosis of pregnancy is not always certain; and it is especially difficult when an examination of the pelvic organs cannot be made.

When a patient presents the usual symptoms of abortion—hemorrhage and pain—we are told in books to make an examination of the uterus; but I am sure to make this an invariable rule is unwise practice. If the symptoms are not severe, active treatment is not called for, and an examination under these circumstances would be likely to do harm. Better to wait either until the symptoms pass away or become more marked.

Before making any examination of the uterus, it is better to decide, as nearly as possible, the next important point: can the abortion be arrested, or must it go on? It is impossible to be perfectly sure on this point in all cases. Where there have been free hemorrhage and severe pain for any length of time, the probabilities are that the abortion cannot be averted; while if there is only slight bleeding, and very little or no pain, then the prospects are that the trouble can be arrested.

Fortunately, while we cannot be positive in diagnosis, we can be certain of the proper course of treatment to pursue. So long as there is any hope of arresting it we should direct our efforts towards that end, knowing that if we fail, the treatment employed will not interfere with the favorable termination of the abortion.

When the history obtained indicates pregnancy, and the patient has the symptoms of abortion, she ought to be put into bed, and directed to rest in the recumbent position, but not constantly on the back, as usually directed. I am satisfied that lying on the back for any great length of time tends to excite uterine action. The influence of position on the reproductive organs is well illustrated in spermatorrhœa, the emissions occurring almost always when the subject is lying on his back. The patient should be directed to change from the back to either side, whenever she feels inclined to do so. Lying on the side, with the lower limbs drawn upwards and forwards, throws the pelvis into a semi-prone position, and removes the pressure from the pelvic organs better than any way, except resting on the knees and chest.

When there is pain and much nervous excitement, an anodyne should be given. Opium and bromide of potassium answer well in most cases. If there is no pain the opium should be omitted. A suppository containing a medium dose of opium and belladonna is sometimes very satisfactory. A fair trial of this line of treatment for twelve or twenty-four hours will suffice to show whether the abortion can be prevented or not. If the symptoms continue, and especially if they increase in severity, then hope of arresting it must be abandoned.

To relieve or modify the pain, and keep the hemorrhage in check, are the indications in the first stage of abortion, or during dilation of the cervix. Opium and bromide of potassium, or the bromide and chloral hydrate, should be employed to keep the nervous system quiet during the day, and to give sleep, if possible, during the night. In some cases the pain is so severe that sleep cannot be obtained short of profoundly narcotizing the patient: then the anodyne

should be given in such doses as will quiet irritability and enable the patient to bear pain without fretting.

Knowing that the ovum cannot be expelled without some pain, we naturally inquire if such free use of anodynes will not retard the process of abortion. My own observations have satisfied me that the first stage of abortion, *i. e.*, dilatation of the cervix uteri, is not retarded by the use of opium or chloral hydrate. On the contrary, I am inclined to think that opium, judiciously given, rather facilitates dilatation than retards it.

The management of hemorrhage is the next indication to be fulfilled. Although occasionally this does not require any special attention, in many cases it needs the most prompt and masterly treatment. The tampon has been universally employed for the control of bleeding in abortion; in fact it has been almost exclusively used. There have been many substances recommended, and a little diversity in the mode of application, but the principle is always the same. Rags, sponges, cotton wadding, and the rubber bag, or colpeurynter, as it is called, are the ordinary materials in use.

Practically, I have found the tampon objectionable in many respects. It controls the hemorrhage partially, but very seldom completely. It is troublesome to use, both to physician and patient. It must be renewed frequently, because if left in situ for any length of time decomposition occurs to an offensive and dangerous extent. I believe that septicæmia, one of the dangers in abortion, is liable to be induced indirectly by the use of the tampon. These objections cannot all be raised against the colpeurynter, as it is easy to introduce and remove, and does not excite decomposition; but what is equally unfortunate, it does not answer the purpose. The rubber bag in the vagina will not control hemorrhage unless it be distended so as to make strong pressure on the vaginal walls and pelvic organs generally. This gives so much distress by exciting pelvic tenesmus that it cannot be borne.

My experience with the vaginal tampon being unfavorable, I have abandoned it altogether. I now trust to the natural mode of controlling or retarding uterine hemorrhage, that is, the formation of coagula in the vagina. To accomplish this I place a compress on the vulva, securing it by the ordinary T bandage. If this fails to keep the bleeding within the bounds of safety, I then tampon the cervix uteri. This is done either by using a sponge tent, as suggested by Sir J. Simpson, or by crowding an ordinary piece of sponge into the cervix with the uterine dressing forceps; or what is better than either, though not always possessed by the practitioner, the hydrostatic dilators.*

The advantages of the cervical tampon over the vaginal are these: the cervical can be introduced and removed through the speculum with the greatest facility, and without much pain to the patient. It more thoroughly controls the hemorrhage, and does not cause vesical and rectal tenesmus. It does not cause decomposition to the same extent. It helps to dilate the cervix, which is desirable; and by damming back the blood into the uterus it separates the attachments of the fetal membranes from the uterine walls. There is but one objection to the cervical tampon, that it slips out of place unless great care is taken. As the os dilates, the dilator gets loose, and will come away. To prevent this, the water in the dilator should be increased from time to time; but this requires the presence of the physician at short intervals, which is not

always convenient. To overcome this objection the dilator should be distended as far as possible, and then fastened to a bandage round the body, in the same manner that surgeons tie a catheter fast in the bladder.

In using the dilator, the greatest care should be exercised in introducing it, so as not to rupture the membranes. It is always desirable to have the ovum expelled whole, as when broken its expulsion by the uterus is often very tedious, and sometimes impossible in any reasonable length of time.

It quite frequently happens that when the os is fully or sufficiently dilated the ovum is not expelled. There is a kind of inertia of the uterus, which permits its contents to remain, and this condition is often attended with hemorrhage. Ergot is then indicated. It will sometimes, but not always, excite uterine contractions, and in that way control the bleeding and expel the ovum. It is at this stage of the process, and at no other, that ergot is useful. I am satisfied from observations that much harm is often done by giving ergot before the os uteri is sufficiently dilated. It is often given to control hemorrhage in the early stage, and generally with ill effects. It rarely if ever controls the bleeding under these circumstances, and is almost sure to increase the patient's suffering if it acts at all. Used at the beginning, it is really worse than useless.

Should there be any delay in the expulsion of the ovum after the os is fully dilated, it is best to employ mechanical means to empty the uterus. The textbooks recommend that the ovum be removed by the finger; and if it cannot be reached by an ordinary digital examination, that the hand should be introduced into the vagina. To those who have practiced this manipulation it is unnecessary to say that it is at all times difficult and sometimes unsuccessful. In abortion in the earlier months of pregnancy one finger is all that can be admitted into the uterus, and this is insufficient to seize and remove the ovum. All that can readily be done is to detach the ovum, break it down, and then trust to its being expelled. When the uterus is larger, as at the end of the fourth month, two or more fingers can be introduced, if the hand is in the vagina; but then the fingers are too short to reach the fundus uteri and scoop out the ovum; and it is seldom that it can be seized even with two or more fingers. And to make this attempt at delivery, it is almost necessary to give chloroform, which adds delay and danger to an operation frequently ending in failure.

After having faithfully tried this standard practice, I have abandoned it for what has proved to be better. When the ovum is retained after dilatation of the os, I remove it through the speculum, by means of forceps and curette. The patient is placed in the semi-prone position, and Sims' speculum introduced; the anterior lip of the os is seized with a tenaculum forceps, and the cervix drawn downwards and forwards. An ordinary dressing or bullet forceps is then carried into the uterus, and the ovum seized and brought away whole or in part. If only a part of the ovum is removed by the forceps, which is frequently the case, then the curette should be introduced, and the contents of the uterus thoroughly and rapidly scooped out. The instrument which answers best for this purpose is the curette of copper wire, without a cutting edge, described in Thomas's work on diseases of women, but it requires to be very much larger. In using this instrument with reasonable care, no injury can be done to the uterus.

The uterus usually contracts promptly, to an extent

* For description and mode of using this instrument I refer to the *American Journal of Obstetrics and Diseases of Women and Children*, May, 1873, p. 92.

sufficient to prevent hemorrhage, when its contents have been removed by the curette. If in very rare cases hemorrhage continues even when the uterus is perfectly empty, then ergot is indicated, and should be used without delay. If that fails to produce contraction, the uterus may be tamponed with sponge or cotton. Should the bleeding still persist, cotton saturated with persulphate of iron may be used. Dr. J. Marion Sims' method of using "iron-cotton," as he calls it, as a tampon to arrest uterine hemorrhage is the best. He uses a piece of whalebone, as long as a uterine sound, tapering to a point, and curved near the end. According to the length of tampon required, that extent of the whalebone is smeared with lard, and then wrapped with layers of "iron-cotton" until the tampon is the size required. It is then carried up to the fundus uteri, and held in place, while the whalebone is withdrawn. If the uterine tampon inclines to come away, a pad of cotton placed in the vagina will hold it in place. In ten or twelve hours the tampon may be removed.

The rules of practice may be very briefly recapitulated:

1. Where the symptoms of abortion are slight, and of short duration, efforts should be made to arrest it.

2. During dilatation of the os opium should be given, if there is any call for it, and ergot should be carefully avoided.

3. Hemorrhage should be controlled by tamponing the cervix, the hydrostatic dilator being the best for that purpose.

4. When the os is fully dilated, and the ovum is not promptly expelled, after the use of ergot, it should be removed by the forceps and curette.

5. Post-partum hemorrhage should be arrested by ergot and the intra-uterine tampon.

The inflammation of the uterus, peritonium, or cellular tissue, which may arise, should be treated on general principles.

GRADUAL DILATATION OF STRICTURE OF THE URETHRA ON THE PRINCIPLE OF THE "MULTIPLE WEDGE."

By JOHN. S. COLEMAN, M.D.,

AUGUSTA, GA.

As both internal urethrotomy and divulsion are occasionally followed by such serious consequences, a new method of gradual dilatation must meet the approval of those members of the profession who treat cases of stricture. A gentleman applied to me for relief from retention of urine. Failing to introduce an ordinary catheter, the stricture being in the membranous portion of the urethra, I took one of Gouley's whalebone guides and passed it into the stricture, but not into the bladder. The effort relaxed the spasm sufficiently to admit of his voiding his urine. With the view of eliminating this element of trouble, I directed him to make use of an enema of thirty drops of laudanum just before his next visit. (It is my habit to use quinine freely during the treatment of stricture, as a prophylactic against urethral fever.) On the third day he returned, and I readily introduced into his bladder one of the whalebone guides; after allowing it to remain a few moments the idea occurred to me that I might pass another down by its side, which, with some difficulty, I succeeded in accomplishing. At the third sitting I introduced four of the guides. At the fourth I introduced two guides, together with three gum-elastic bougies of Gemrig's scale; Nos. 3, 4, and 6, the whole

equalling in bulk about a No. 7 English scale. On a previous occasion, in a case of retention, I succeeded in relieving the patient by the simple introduction of one guide.

In reply to my communication to Dr. Gouley on the subject, he says: "I have myself wedged in two and sometimes three of these bougies side by side, and have thus rendered otherwise impassable strictures amenable to ordinary dilatation. Three years ago I had some whalebone probe-pointed bougies made very small (capillary) for the first two inches from the vesical end, and thence increasing gradually to Nos. $\frac{1}{2}$, 1, 2, 3, and 4, so that I could accomplish more dilatation with a simple bougie at one sitting than I could with two or three ordinary whalebone capillary bougies introduced side by side." In closing his letter he says: "I would suggest also that a small tunnelled sound or catheter be used after having passed three or four capillary instruments, and while they are still in position. In this manner the wedge-principle could be carried out to the point of divulsion if desirable."

It is quite evident to my mind that Dr. Gouley, though he had used the "two or three guides side by side," he did not appreciate the principle involved, for he abandoned it for the "whalebone probe-pointed bougies." The name of this little whalebone instrument designates the use for which it was intended by Dr. Gouley, viz.: a "guide" upon which to pass a "tunnelled grooved sound" into a stricture, to facilitate the operation of external urethrotomy. My plea is that the "wedge-principle" will obviate, in most cases, the necessity for divulsion, internal or external urethrotomy. I therefore claim priority, if not in actual use, in first appreciating and making known the multiple-wedge principle in the treatment of urethral stricture. I am aware that many medical men will at once say that there is nothing new in the wedge; that all conical bougies are wedges. This I grant, but claim that it is a new application of the *principle* of the wedge in the treatment of stricture.

It ought to be a self-evident proposition that it is easier to introduce singly the component parts of a wedge than to introduce it as a whole. Take, for example, a No. 12 conical bougie, even capillary at its point, and attempt to introduce it into a stricture, where is the point of friction and resistance? Is it not around the entire circumference of the stricture?

Diminish the size of the instrument and in a direct ratio you diminish the amount of resistance. After having passed into a stricture one of these whalebone guides, the second has to overcome the friction and resistance of but one-half the circumference of the stricture and the *line of contact* with the other bougie.

Now that we have passed these two, we have a groove in front and behind them, through which we can readily pass the third and fourth, having now to overcome the resistance of but one-fourth the circumference of the stricture and the *two lines of contact* with the instruments already in position.

For these guides the profession owe Dr. Gouley a lasting debt of gratitude.

FIVE WORKS—four German and one English—were entered in competition for the prize offered by the German Empress for the best hand-books on technical military surgery. At the suggestion of the judges, it was ordered that the prize of 2,000 thalers should be divided; that 1,000 thalers be awarded to Dr. Friedrich Esmarch, Professor at Kiel, and 500 thalers each be given to Surgeon-Major G. A. Porter, of England, and to Dr. Joseph Landsberger, of Posen.

PARALYSIS OF THE ACCOMMODATION OF THE EYE FOLLOWING AN ATTACK OF DIPHTHERIA.

By P. A. CALLAN, M.D.,

ASSIST. SURGEON NEW YORK EYE INFIRMARY, N. Y.

THE two cases here presented occurred in the service of Dr. Henry D. Noyes, at the N. Y. Eye and Ear Infirmary. Considering the large amount of diphtheria in the city at present, and the few cases of eye complications seen in the present epidemic, we think they may be of interest to the profession.

Mary L., æt. 11, Paterson, N. J. The patient about the middle of September had an attack of diphtheria, from which she apparently recovered, and she enjoyed perfect health up to the 1st of November, when she complained of not being able to see distinctly any object, being blurred and hazy, so that she was obliged to discontinue going to school. The mother of patient noticed about the same time that she spoke through her nose and quite indistinctly; having an impediment in her speech as the mother designated it. This condition of affairs having remained unchanged, she was brought to the city, November 16, when she came under our observation for the first time. Patient's physique fair; when spoken to she readily responded, but her pronunciation was quite defective, and she spoke through her nose. Tongue and pharynx normal in appearance, the uvula quite long, and when patient was made to articulate it moved very slightly. Patient had some difficulty in swallowing. The pupils of both eyes were slightly dilated; the vision of both eyes was $\frac{7}{8}$ with glasses, + $\frac{1}{2}$ vision = $\frac{2}{20}$. At a distance of 10 inches she could not see ordinary print, and it was with difficulty that she managed to make out Snellen 6 $\frac{1}{2}$ at the ordinary reading distance, which should be read at 6 $\frac{1}{2}$ feet, but with her proper correcting convex glass she could read with comparative ease.

Ophthalmoscope showed a hypermetropic build of eye and a normal fundus. Patient had a hypermetropic of $\frac{1}{2}$.

Treatment.—Tonics, with local application of electricity. November 30, patient's vision has very much improved, but the voice remains much the same. Prognosis very good.

Joseph M., æt. 4 $\frac{1}{2}$ years, N. Y. City. Patient had an attack of diphtheria about October 1st, from which he slowly recovered. About five weeks from his attack, the mother noticed that he could see small objects which were in close proximity, small playthings for instance, would fall out of his hands and he could not find them; distant objects on the other hand were seen. At the same time he had hemiplegia of the left side, with partial ptosis of the left eye. November 19, the patient came under our observation for the first time, when we found paralysis of ace, in addition to the others just mentioned. Ophthalmoscopic examination showed the eye to be hypermetropic in build, and the fundus perfectly normal. Patient was treated as case No. 1. November 27, vision and ptosis much improved, hemiplegia much the same.

NOVEMBER 30, 1874.

PERIODICAL VESICULAR ERUPTION, FOLLOWING THE BITE OF A RATTLE-SNAKE.

By HENRY G. PIFFARD, M.D.,

CLINICAL PROFESSOR OF DERMATOLOGY, UNIVERSITY MEDICAL COLLEGE, N. Y.

THE following case, observed nearly nine years ago, appears to deserve record, especially as I have met with nothing similar to it in the interval:

On March 29th, 1866, I was called to see Mary O., aged 19 years and married. I found her suffering from an acute disorder, the details of which need not interest us here. When about to feel her pulse I noticed that the tendon of the flexor carpi radialis of the right side was quite tense, the hand somewhat drawn up. In addition, I observed an eruption of small vesicles upon the integument lying between the metacarpal bones of the thumb and index finger. The vesicles were four in number, about the size of a No. 1 bird shot, filled with a slightly yellowish fluid, and were situated upon a somewhat reddened but not raised base. Upon inquiry, I obtained the following history. Six years before she was travelling with the "side-show" of a circus, and it was a part of her business to perform as a snake-charmer, daily exhibiting a number of rattlesnakes, which she took out of a box in which they were confined, and freely handled. On one occasion one of the snakes bit her, its teeth entering both the palmar and dorsal surfaces of the proximal phalanx of the right thumb. The bite was followed by severe pain and great swelling of the forearm and arm nearly to the shoulder, accompanied with discoloration of the integument. In addition there was marked contraction of some of the flexors of the hand, and also nausea. From this accident she appeared to have made a good recovery. Three months later, however, there appeared upon the integument, covering the metacarpal bone of the right thumb, an eruption of three or four small vesicles, accompanied with a "beating" pain at the site of the eruption, together with contraction of the flexors and inability to extend the hand. In the course of a few days the vesicles dried up and the other symptoms disappeared. Since that time and up to the date of my visit she has had a return of the eruption, with contraction of some of the flexors, *every three months*. Her husband stated he could confirm this statement for the previous two years (the period of his acquaintance with her).

April 7th, 1866.—The vesicles have disappeared, leaving only small reddish spots which marked their site. The flexor contraction has subsided.

June 30th, 1866.—Her husband called to inform me that the eruption had returned two days previously. Upon visiting her I found the condition similar to that observed March 29th.

Oct. 1st, 1866.—To-day she showed me the vesicles again. They had appeared several days before, and were on the decline; in fact, nearly dried up. The flexor tension was slight but distinct.

On several occasions since I have seen a repetition of the phenomena described above, occurring with the same *periodical* regularity. For several years I lost sight of this case, and did not meet her again until about a year ago, at which time she informed me that for the last three or four years the vesicles had not returned with their previous regularity, indefinite intervals always greater than three months intervening between the eruptions, and that during the last seven or eight months there had been no reappearance of the vesicles.

GERMAN COMMISSION TO THE PHILADELPHIA EXHIBITION.—Dr. Jacobi, of the German Department of Commerce; Dr. Kruger, the Hansaatic representative, and Dr. Neidhardt, member of the Federal Council for Hesse, are among the commission of ten appointed by the Imperial Government to represent Germany at the Centennial.

The lesions and symptoms described above are evidently dependent upon neurotic influence, but the case, so far as my own experience is concerned, is unique; and I know of nothing similar to it except the *periodical* neuralgias which are said to follow wounds inflicted by some of the *felinidæ*. Dr. Livingstone says that a wound from a lion's tooth is generally followed by great sloughing and discharge, and pains are felt in the part *periodically* ever afterwards.*

Original Lecture.

UNIVERSITY MEDICAL COLLEGE.

CLINIC FOR DISEASES OF THE EYE AND EAR.

By PROFESSOR D. B. ST. JOHN ROOSA, M.D.

PHONOGRAPHICALLY REPORTED BY J. M. HERVEY, M.D.

Wednesday, Dec. 2, 1874.

GENTLEMEN:—I have brought a case here to-day that will illustrate a disease you will all have occasion to treat—a disease of which I have already spoken, and of which I wish to speak more fully than I have hitherto.

OPACITIES OF THE CORNEA FROM TRACHOMA.

CASE I.—Woman, aged about 60. This is one of Dr. Agnew's patients, and it is through his courtesy that she came to-day for the purpose of illustrating what I have to say. I want you to look at the cornea and see the opacities there, and if you look at it carefully, you will be able to see that those opacities must be deeper than the epithelium, and deeper than Bowman's membrane; they are in the true structure of the cornea, and I am sure if the true history of her case could be obtained, we should find that the beginning of this trouble was a catarrhal conjunctivitis, which finally resulted in trachoma. You see one consequence of the trachoma in the opacities of the cornea—for the keratitis which caused this was induced by the pressure of roughened lids on the cornea—and if you look at the eyelid you will see another consequence; you will see that the eyelid fits over the eyeball too tightly to give free space for the eyeball to work beneath the lids; you will see a little shortening of the palpebral fissure, and shrinking of the cartilage—you can see that without turning the lids at all. The conjunctiva is the mucous membrane which lines the lids and covers the front of the eyeball. It is a mucous membrane very richly supplied with vessels and nerves. In that portion of the conjunctiva that we call the palpebral, that is the portion that lines the lids, are numerous furrows, which might be represented by little lines like those on the blackboard. It also has little elevations, called papillæ, but when you turn to the ocular conjunctiva, that which covers the eyeball, you find none of the papillæ. This mucous membrane, so richly supplied with nerves and vessels gets easily inflamed. How? By exposure to cold; by getting the feet wet, and so forth; a man works in the dust and the dust gets into his eyes, and if not thoroughly removed it irritates the nerves of the conjunctiva and causes catarrhal conjunctivitis. What is catarrhal conjunctivitis? It is inflammation of the conjunctiva which creates an increased secretion of mucous and lachrymal fluid, and such a patient has watering

of the eyes, and the blood-vessels being enlarged and pressing upon the ball he has a feeling as though sand were in his eyes. This is the first stage, and if properly treated it goes no further; but suppose it goes on: suppose with this mucus we have a little pus mingled, then we have blennorrhœa; but suppose it goes on still further, and all the elements secreted are pus, then we have pyorrhœa. These are the three stages of catarrhal conjunctivitis, but they do not always follow each other in such a way that we can distinguish one stage from the other. Suppose a man gets catarrhal conjunctivitis and it runs on, it does not necessarily run into pyorrhœa or blennorrhœa, but it may pass into trachoma; that is what this woman had at the commencement of this trouble in the cornea. Trachoma or granular lids, so called, is one of the most common of the diseases of the eye. Trachoma means simply a *rough tumor*—the name does not describe the disease at all, and granular lids is another improper name. When a man gets an ulcer on his leg or any other part of his body, and that ulcer does not heal properly, we call that proud flesh, in common language, or exuberant granulations, in technical language, but that is not trachoma. For the so-called granular eye-lids are not cases of exuberant granulations, such as we have in an unhealthy ulcer. If they were so, the lids would constantly adhere to the cornea.

If we had trachoma of the cornea it would become cloudy, and complete loss of sight would occur. The inflammatory process resulting in trachoma, is what microscopists call increase of tissue, or proliferation of tissue; the latter term is much used by pathologists at the present day. By this process of new formation, these little fissures in the conjunctiva are filled up, and these papillæ become enlarged. Trachoma, therefore, or granular lids is simply a filling up of the fissures in the conjunctiva, and an enlargement of its glands or papillæ. This is caused by catarrhal conjunctivitis, which was either not treated at all, or perhaps treated so severely or improperly that the inflammation increased.

The trachomatous formations, themselves consequences of disease, irritate the cornea, set up inflammation which makes it opaque, and at times produces a condition of vascular cornea called pannus, which may go on until the eye be destroyed.

How shall we treat catarrhal conjunctivitis? If you had a case of much increased secretion from the conjunctiva, some redness, etc., the first thing you would do would be to use astringents—that is perfectly proper. Turn up the lids and apply nitrate of silver and neutralize it afterwards by salt and water, but if you do not see the case in the first stage do not use the nitrate of silver. What astringent would you give a patient to use? "Sulphate of zinc;" what else would you do? I would not use any constitutional treatment whatever in catarrhal conjunctivitis. It is a disease which usually comes on from causes which have nothing to do with the constitutional condition. What other local means are there, what else besides astringents? The free use of cool or luke-warm water during the day will be found very soothing. The water may be gently thrown on the closed lids from a basin full of it. The lids will stick together in the morning—what will you do for that? Put a little simple cerate on them at night on going to bed. That is the way you would ordinarily treat catarrhal conjunctivitis, and if treated in that manner you would seldom have trachoma following.

As to blennorrhœa and pyorrhœa, I will pass over them for the present. But suppose you have now

* Travels in Africa, page 15, New York, 1858.

a case of trachoma with those elevations on the conjunctiva looking like the spawn of fish. How will you treat that? With sulphate of copper: have a nicely rounded stick of sulphate of copper, and use it once a day. How many months do you suppose it would take to cure a case of trachoma, well developed? It will take from four to six months at the least. You must not tell your patient it will be well in a month or two. If you do, he will be disappointed at the end of that time, and will go round to other doctors and say that you don't know anything about it. But there are very many complications in trachoma which must be carefully noticed, of which I will not now speak

CYCLITIS FROM INHERITED SYPHILIS.

CASE II.—Gentlemen, I have lectured about sympathetic ophthalmia or sympathetic inflammation, and I want you to notice in this little man that he has lost his left eye. It was removed one year ago on account of sympathetic irido-choroiditis, and now we find that this boy in spite of that operation has cyclitis. You see that he has no teeth in his upper jaw, and but few in his lower jaw. He has the evidences of mal-nutrition, and some constitutional disease by inheritance of the nature of which I will talk to you when his mother is not present. He is now suffering from inflammation of the ciliary body, an inflammation that any child with two eyes may have with such a constitution as he has got. I show him as a fine example of cyclitis with constitutional taint. The treatment is locally atropine: constitutionally, cod-liver oil, mercury, iodine of potassium, good food, good air, etc.

CASE III.—Gentlemen, here are three cases of inflammation of the middle ear—suppurative inflammation of the middle ear. This child has had “a running from the ears” ever since it was a baby, and is now eight years old. This running from the ears originated from catarrh of the tympanic cavity. It is otorrhœa, so called; we call it a chronic suppuration of the middle ear—a name which describes the nature and situation of the disease, and therefore tells all about it. She has been under treatment at the Manhattan Hospital over a year. The prognosis depends upon the amount of destruction the disease has produced. If, as in this case, the ossicles are not gone, the prognosis is favorable; but if the bones are swept away and the cavity stript of its furniture the prognosis is very unfavorable. If the patient has suffered the loss of but one bone a cure may be effected; you only have to keep the ear clean. Simple a thing as cleansing the ears is, but very few know how to do it. I will show you how it is done. With the thumb and finger of one hand you draw the ear upwards in order to straighten the canal, and with the other hand you syringe the ears, as you see me do. Now, gentlemen, all of you who honored me with your attention know how to cleanse ears. Then you should examine the ear with a speculum to see if it is properly cleansed. After it is properly cleansed take a little cotton on a cotton holder, and dry it thoroughly. There will yet be something to do. This tympanic cavity is so small, and there are so many places in it in which pus might accumulate in spite of syringing, it will be necessary to use Politzer's method, for the purpose of forcing out these little plugs of pus and mucus. The main thing is to keep the ears perfectly clean, then some astringent application may be used.

The other two little boys have had running from the ears ever since they recovered from scarlet fever. The ears were perfectly well before they took scarlet fever, they began to inflame after they were well of the fever. The membrani tympani is such a thin

membrane, although it has three layers, that it may break through without pain. This child never had any ear-ache, the first thing noticed was the suppuration. The trouble commencing in the pharynx went up through the Eustachian tube and broke through the drum-heads on each side.

One of the many consequences of disease of the middle ear is meningitis, although there are many persons who seem to think this trouble in the ears of little account.

INFLUENCE OF A PROPER DRAINAGE AND WATER-SUPPLY UPON THE MORTALITY OF A TOWN.—In the twelve years immediately preceding the completion of the drainage and water-supply system of Salisbury, England, the yearly mortality amounted to 27 per 1,000. During the twelve years following, the mortality fell to 20 per 1,000, and during the last three years it was only 17 per 1,000. During the latter period typhoid fever was almost unknown, and the cholera, which in 1849, or before these changes had been made, was fatal in nearly 200 cases—was only fatal in 14 cases in 1854, the time at which the works were under completion. In 1866 there was not a single case in the town.—*Geigel's Offentl. Gesundheitspflege.*

CATHETER IMPACTED IN THE FEMALE PELVIS.—At a recent meeting of the Royal Medical and Chirurgical Society, Mr. Barwell reported the case of a female whom he found suffering from a large abscess over the hip, with a sinus in front of the anus, all of which seemed to have originated in an instrumental abortion produced upon her twenty months previous. A subsequent examination, made after the abscess had been evacuated, revealed the presence of a gun-elastic catheter, lying up between the uterus and bowel. A small opening was detected communicating with the rectum, through which the catheter was forced, and then drawn out at the anus.

CASE OF CHRONIC ARSENIC POISONING.—HOLM, in the *Upsala läkareförenings förhand.*, describes a dozen cases of arsenic poisoning from the wall-paper, lamp screens, and curtains of dwelling-houses. In these cases the etiology was evident, and the symptoms very distinct and characteristic. The latter were chiefly the following: headache, with a sensation as of a ligature tightly embracing the head; giddiness and fainting; occasionally a faltering gait and a fog before the eyes; the latter were often red and painful; nausea, occasionally vomiting, especially in the morning. Frequently the appetite was bad, the tongue furred, and there was constipation. The sleep was often disturbed by dreams. There was general sinking of the corporeal and mental strength; dulness of the memory and of the power of thought. The appearance was cachectic, and there were occasionally tremors and nervous weakness. It happened pretty constantly that the symptoms rapidly disappeared when the poisoned room was vacated for a while, or the arsenical substances were removed; they rapidly returned, however, when the patient reoccupied the room. Poisoning also occurred where arsenical paper had been covered over with paper that was free from this substance, or where the arsenic was present in oil colors. The author is of the opinion that arsenic is present in the air of such rooms in the form of arseniuretted hydrogen, and that it is more probably absorbed into the human body by way of the skin than by the respiratory organs.—*Lor-diskt Med. Arkiv.*, 6 No. iii.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 23, 1875.

PERMANENT MEMBERSHIP IN THE STATE SOCIETY.

PERMANENT membership in the Medical Society of the State of New York is a subject which always invests itself with interest on the eve of every meeting of that association. Not only has it an interest in itself, but as part of a system of society organization, a discussion of its merits commands more or less the attention of the profession at large.

It is pretty generally known that but eight permanent members to this Society are elected each year. This being the case, there is always a considerable amount of struggling on the part of each eligible candidate to gain that honor. It would be strange indeed if there were not many abuses connected with the system of election, and much reason for considerable dissatisfaction. The main claim of injustice in the election of permanent members does not rest so much upon the complaints of individuals as upon the inequality of representation from the different districts. We propose in the following remarks to view the abuses from this stand-point, and suggest what to us appears to be a reasonable remedy.

The difficulty to which we refer is, for the most part, due to a rigorous adherence to the original plan of organization of the Society, and a disposition to ignore the fact that some districts have grown very unequally in population and representation. In other words, we still hold to the original eight Senatorial Districts, notwithstanding the fact that the law of the State, in order to establish the proper ratio of representation, has divided it into thirty-two districts.

We have before us two elaborate tables, which show the Society as it is and as it might be. These tables have been prepared with great care by a gentleman who has given a great deal of time and attention to society organization, and they may be relied upon as accurate. Table I. shows the counties composing each of the eight Senatorial Districts into which the State was divided by the law of 1836. The number of

county medical society members (2,836) by counties and districts; the number of delegates (139) to which each county and district is entitled; the number of persons eligible to election to permanent membership (181); the number of permanent members (327), and the population of each county and district. Table II. shows the same classes, but the 60 counties of the State are divided into the existing 32 Senatorial Districts, and the corresponding numbers are given for each county and district.

In the original senatorial division into eight districts, as shown in the first table, the first district is made up of the counties of New York, Kings and Richmond, and has a total membership in county medical societies (as given in the last vol. of the *New York Medical Register*), of 755. From these counties are sent 31 delegates from the societies, one each from 4 medical colleges and 5 from the N. Y. Academy of Medicine, making a total of 40. This district has 48 permanent members. The 5th district, consisting of six counties, Oneida, Madison, Oswego, Lewis, Jefferson and Otsego, has 244 county society members, 14 delegates, and 40 permanent members. The second district (nine counties), Queens, Suffolk, Westchester, Rockland, Putnam (reported as having no society), Orange, Sullivan and Ulster, has 349 county members, 15 delegates, 40 permanent members. The 3d district has seven counties, Albany, Delaware, Green, Columbia, Rensselaer, Scholarie and Schenectady, has 288 county members, 15 delegates, and 47 permanent members. The 4th district has eleven counties, viz., Saratoga, Montgomery, Hamilton, Washington, Warren, Clinton, Essex, Franklin, St. Lawrence, Herkimer and Fulton, has 289 county society members, 14 delegates, and 36 permanent members. The 6th district has 10 counties, Chenango, Broome, Tompkins, Chemung, Tioga, Steuben, Livingston, Alleghany, Cattaraugus, and Schuyler, having in all 345 county society members, 12 delegates, and 36 permanent members. The 7th district, 7 counties, Wayne, Ontario, Yates, Seneca, Cayuga, Onondaga and Portland, has 263 county members, 13 delegates, and 40 permanent members. The 8th district has 7 counties, Chautauqua, Erie, Genesee, Monticue, Orleans, Niagara and Wyoming, with 303 county society members, 15 delegates and 40 permanent members.

Let us apply a little comparison to these figures. It is an established principle that things which are equal to the same thing are equal to each other. Each of these eight districts is entitled to two permanent members each year—therefore the 244 county society members of the 5th district are equal to the 755 of the 1st district; or to put it in another form, 2 permanent members being a common factor, 244 in the 5th equal 755 in the 1st, 349 in the 2d, 288 in the 3d, 289 in the 4th, 345 in the 6th, 263 in the 7th, and 303 in the 8th. Applying the same method to the delegates, we have the 12 delegates of the 6th district equal the 13 of the 17th, the 14 of the 4th and 5th, the 15 of 2d and 3d

the 16 of the 8th, and the 40 of the 1st, that is, $12 = 13 = 14 = 15 = 16 = 40$. Is there any reason for this inequality, and is there any easily attainable remedy?

In the beginning of the life of the Society, it was proposed to elect extraordinary members, who were to be such as the Society deemed worthy of "respect and attention," who were to have all the rights and privileges of ordinary members, except those of voting and being elected to office. It does not appear from the records that any were elected. In 1813 the law gave the Society the power to elect two permanent members each year from the State at large, who were to be "eminent and respectable." The purpose of doing honor to eminent and respectable practitioners is thus made clear. As only two could be elected in any year, all desired the honor. In order that more might attain unto it, in 1845 a law was passed by the Legislature permitting the election of two annually from each of the eight Senatorial Districts then existing. The result has been that the number elected in each year being the same for each district, and the districts (however they may have been in 1836), having grown at unequal rates, or at least the first having grown much faster than any other, we have the very glaring inequality that has just been exposed.

In 1867 a delegate whose name had been five years on the list of those declared eligible to election as permanent members, proposed to amend the by-laws so as to increase the number to be elected annually to six in each Senatorial District. This being declared out of order, he asked the Society to request the legislature to authorize such a change. The request was, however, after some debate, "indefinitely postponed."

Relief may not be thus obtained, but is there no way of rendering equal justice to all parts of the State? We propose to obtain a remedy by electing the permanent members from the present Senatorial Districts, of which there are thirty-two, and which are as nearly equal in population as may be,—instead of from the eight of 1836.

This will simply require that the sixteen permanent members be elected each (even-numbered) year from the districts with even numbers, and from those with odd numbers on the odd years. If this were done, the county of New York would, each even year, elect three, and each odd year two such members. Kings would elect one each year, and Albany, Oneida, Monroe and Erie would each elect one every other year. Under this arrangement, the Twenty-third Senatorial District, Chenango, Delaware and Schoharie counties, has the largest medical population, 115. The smallest is the Thirty-second, viz., Cattaraugus and Chautauqua counties, which have only fifty-seven county members. The five of New York will average $103\frac{1}{2}$ —the two of Kings, 107.

This plan, while it will not remove the present inequality of representation, will prevent its becoming more glaring.

How can it be carried out? Unfortunately it will

require an authorization from the legislature. The law of 1845 runs as follows: "It shall and may be lawful for the Medical Society of this State to elect annually such a number of permanent members as they may from time to time determine by their by-laws, not to exceed two annually from any one Senatorial District." This might be amended so as to read as follows:

"The Society may annually elect from those who have served as delegates, and have been nominated and declared eligible at a previous annual meeting, not more than sixteen permanent members to be chosen from the thirty-two Senatorial Districts now existing, in alternation by even and odd numbers, the candidates being residents of the districts from which they are elected, except when a county contains two or more districts, in which case residence shall be restricted to the including county only."

The law being thus amended, the by-laws of the Society could be made at once to conform to it.

We believe that the time has come when some such change should be made. The dissatisfaction in regard to the election of permanent members is growing year by year, and the proposition which we make may be one of the means to arrest it. At least, on the principle of fair play, it should commend itself to the serious consideration of every one interested in the prosperity of the Society.

THE HEALTH OF OUR PORT.

FROM the third annual report of Dr. S. O. Vanderpoel, Health Officer, we have the gratification of knowing that less sickness of a transmissible character has entered our port than during any season for several years past. One of the chief causes for this state of affairs is a decrease of the number of immigrants, but another cause, to which too much importance cannot be attached, is the enforcement of regulations not only tending to maintain the health of passengers, but to their proper sanitary inspection before leaving European ports. Dr. Vanderpoel very properly lays great stress upon these points, and shows his thorough appreciation of the higher functions of his office. The education of the owners of vessels in regard to the importance of preventing disease has been attended with such satisfactory results that, in place of the former opposition to quarantine, there is a desire to encourage him in the performance of his official duties. This is certainly a very gratifying exhibit, and reflects great credit upon the judgment and skill with which the duties of the office have been performed.

REDUCTION OF SALARIES IN THE HEALTH BOARD.

WE learn that the salaries of the Sanitary Superintendent, Registrar of Vital Statistics, and the Sanitary Inspectors, have been reduced to bring the expenditures within the range of the appropriations for the coming year. This may have been a necessity, but have the Health Commissioners borne their share in the reduction?

Reviews and Notices of Books.

THERAPEUTICS AND MATERIA MEDICA; A SYSTEMATIC TREATISE ON THE ACTION AND USES OF MEDICINAL AGENTS, INCLUDING THEIR DESCRIPTION AND HISTORY. By ALFRED STILLE, M.D., Prof. Theory and Practice of Medicine, etc., Univ. of Penn. Fourth edition, in two vols. Philadelphia: H. C. Lea. 1874. 8vo, pp. 1944.

THE work before us, after being out of print for some time, makes its appearance as a fourth edition. As a treatise its reputation is already well established, and many of our readers are practically acquainted with its claims to the front rank as a guide to the study of one of the most important yet very much neglected departments of our science.

In the present issue nearly three hundred pages have been added, while the chapter on Electricity has been almost entirely rewritten. The original classification of medicines remains the same, and, while there will always be some who will object to any arrangement not of their own making, we are willing to accept the judgment of the author as well founded.

All works of this class must necessarily be more for reference than continued study, and when one consults them, he is fortunate if, in his search for information concerning any particular drug, he is rewarded by a knowledge concerning it which is founded upon observations of fact and based upon clinical experience. There is no branch of medicine so given to theory as materia medica, and no department which, practically speaking, has less need of it. Our ideas of the actions of drugs are founded for the most part on empiricism, and any discoveries of good effects which we have made have been more by chance than calculation. Clinical experience, after all, is the real element of value in the estimation of the properties of our remedies, and it is one of the features of this work that so much attention is paid to it, and so much pains taken to arrive at conclusions independent of any preconceived opinions. While this is the case, there is no desire to ignore the opinions of others, and no disposition to neglect the study of therapeutics in its most comprehensive sense, to view each remedy not only in its clinical but physiological, physical, and chemical relations.

The present edition is fully up to the requirements of the times, and is fully able to maintain the enviable reputation which the work has long since gained for itself as a first-class authority.

THE BREATH AND THE DISEASES WHICH GIVE IT A FETID ODOR, WITH DIRECTIONS FOR TREATMENT. By JOSEPH W. HOWE, M.D., Author of Emergencies, Clin. Prof. of Surgery in Univ. Med. College, etc. New York: D. Appleton & Co. 1874. 12mo, pp. 108.

In this little work the author has taken the pains to arrange in systematic form the various diseases or conditions which are associated with or give rise to fetid breath. Under the head of general causes of this condition he mentions the lack of power to eliminate "metamorphosed nitrogenous tissues through the mucous membrane of the intestine," and also the tardy passage of decomposing detritus through the bowels, or defective elimination of excrementitious substances by the kidneys. Again, under the head of systemic causes he mentions mental emotion, and in the course of remarks upon the effects of the latter, relates the usual anecdotes in illustration, which are very good to tell, but very hard to believe. He

then refers to some cases of his own, which are to the point, and, as far as they go, prove the theory. Next in order follows the consideration of fetid odors depending upon dyspepsia, constipation, bad teeth, ulcers of the mouth, follicular pharyngitis, and lastly, upon mineral poisons, all of which subjects are rather indifferently presented.

In the treatment for these different affections there is nothing peculiar to note, except perhaps the number and variety of the different prescriptions which are scattered through the work, and which prove that the author is better calculated to treat these diseases than to write about them.

Progress of Medical Science.

THE TREATMENT OF FISTULOUS SINUSES BY THE ELASTIC LIGATURE.—Mr. Allingham, of London, in a recent article on the above subject, after ascribing to Prof. Dittel, of Vienna, the honor of having brought into general notice the elastic ligature, though the first applications seem to have been made by Dr. Silvestri, of Vicenza, states that he is convinced from experience that there are decided advantages in the elastic ligature over the knife in many surgical cases, and particularly in the treatment of fistulæ. He mentions its use in sixty operations, of which forty were for fistula in ano, five were for hemorrhoids, two for removal of scirrhus breasts, two for varicocele, and the rest for various other diseases. In none did any serious consequence follow the operation, and it was noticed that cases which had been operated upon by the ligature did much better than those which had been treated by the knife, though the patients were under the same hygienic influences. He was careful not to be partial in the selection of cases. He thinks that the probable advantages of the ligature over the knife in ordinary sinuses, are:

1. The operation is commonly painless, and the subsequent suffering, if any, is usually very slight.
2. It is bloodless.
3. There is greater rapidity of cure.
4. The patient need not keep his bed, nor even his room, but may go into the air and drive or walk in moderation.
5. Its peculiar applicability to delicate patients, and those who have a phthisical tendency.
6. There is usually no anæsthetic required.
7. There is a minimum amount of suppuration.
8. And one may add, that the ligature is often very advantageous as a supplement to the knife. *Medical Press and Circular*, December 2, 1874.

THE PHYSIOLOGY OF VOMITING AND THE ACTION OF DRUGS UPON IT.—Dr. T. Lauder Brunton, the present editor of *The Practitioner*, in a highly interesting article on the above subject, submits the following conclusions:—

(1.) Vomiting consists in two factors, viz. (1) the simultaneous compression of the stomach by the abdominal muscles and diaphragm; and (2) the opening of the cardiac orifice by the contraction of the longitudinal fibres of the œsophagus.

(2.) When innervation is disturbed, these two factors do not occur together, and thus retching may occur without vomiting.

(3.) The movements of vomiting are correlated by a nervous centre in the medulla oblongata, from which impulses are sent down through various motor nerves to the muscular structures engaged in the act.

(4.) This nervous centre is probably closely connected with the respiratory centre, but is not identical with it.

(5.) It is usually set in action reflexly by irritation of the pharyngeal, gastric, hepatic, enteric, renal, uterine, ovarian, and possibly also by the pulmonary and vesical nerves which come from the periphery towards it. It may also be excited by impressions sent down to it from the brain.

(6.) Vomiting may be arrested in two ways, either by removing the irritant which is exciting the vomiting centre, or by lessening the excitability itself, so that the centre no longer responds to the impressions made on it from without.

(7.) Emetics may be divided into two classes: those which act only on the stomach, and those which act on the vomiting centre also.

(8.) Tartar emetic probably acts in both ways. Tolerance of it is probably due to want of hydrochloric acid in the stomach.

(9.) Emetics may be used to evacuate the stomach and duodenum. They thus remove irritating matters, poisons generated in the stomach by putrefaction, bile, and metals or fever poisons circulating in the entero-hepatic circulation.

(10.) They may be also used to empty the bronchi and gall-bladder, or to cut short epileptic and to prevent ague fits.—*The Practitioner*, December, 1875.

THE PIN-HOLE OS UTERI AS A CAUSE OF DYSMENORRŒA.—In a discussion of the subject of dysmenorrhœa which took place in the Obstetric Section of the British Medical Association, at its last meeting, Dr. Matthews Duncan differed from preceding speakers and from most authors in that he had met with a pin-hole cervix only once in a few years in a large practice, whereas dysmenorrhœa was very frequent where there was no pin-hole os. It was a grievous deformity, and out of all proportion to dysmenorrhœa. Few men had examined more cervixes uteri, probably, than he had during the last twenty-five years, and he found pin-hole cervix to be as rare as an acephalous fœtus; the condition, even where it did exist, did not cause dysmenorrhœa. A pin-hole was large enough to allow a woman to bleed to death within a few hours. It was not a cause of mechanical dysmenorrhœa; the whole theory was fallacious; the same phenomena were to be seen in early abortion. The pains of real dysmenorrhœa were fearful, indicated by cold-sweats, vomiting, and intense agony. It was not a disorder of the external os uteri. The cervix might be cut off without benefit. Mechanical dysmenorrhœa was a disease of a spasmodic character. In the most serious forms women sometimes passed over a period without the least pain, showing that it was not mechanical. Mechanical treatment is most useful in this disorder, but should be employed with great care. Where the general health is deteriorated, there is risk of cellulitis. Mechanical treatment should only be resorted to when the general health is suffering, and the simplest treatment is the best, such as the bougie, as suggested many years ago by Dr. Mackintosh. Many cases were permanently cured by a single passage of a bougie. A well-marked arnoloz is spasmodic stricture of the urethra, where micturition can be accomplished after a bougie has been passed. Spasm of the uterus is the essence of dysmenorrhœa.—*British Medical Journal*.

INFLUENCE OF NUTRITIVE CHANGES AND EXTERNAL CIRCUMSTANCES IN THE PARENT UPON THE DEVELOPMENT OF SCROFULOUS CHILDREN.—In a recent address by Dr. Evory Kennedy, before the Dublin Obstetrical Society, the proposition was put forward that scrofula

is affected by the surroundings and circumstances which modify the human organism, his views being founded upon the fact that "all organizations are not merely variable but varying." The following case was mentioned as an interesting illustration of the manner in which external circumstances may lead to the production of those modifications of the human organism which we collectively term "scrofula," and of a return to the normal condition when the circumstances which had produced the changes had passed away.

A peasant, whose family was liable to scrofulous modification, as seen markedly in his sister and her family, married a woman free from any taint of scrofula, and had two children, who presented none of the characteristics known as scrofula. After their birth the father had an attack of rheumatic fever, which left him with an injured heart, and consequently in straitened circumstances from his crippled condition as a bread-winner. During this period of nipping poverty two other children were born, whose clumsy fingers, thick joints, tumid *alae nasi* and upper lips, together with a strong tendency to glandular enlargements, mark the scrofulous diathesis. After this time the mother had an annuity left her, which once more placed them in comparative plenty. Two more children were born, approaching the healthy type of the two eldest, and comparatively free from the characteristics of the middle pair. When the family are gathered together, the history of the married life of the parents can be read in the physiques of their offspring.—*Br. Med. Jour.*

ADIPOCERE.—During the past summer an example of the conversion of the tissues of the body into that spermaceti-like substance known as adipocere occurred in the body of a woman which had been dredged from the Thames, in London after having been embedded in the mud for an unknown period—probably two or three years. Upon rapping, the body was hard and perfectly resonant, and the whole of the internal organs were converted into a solid mass, which, like the rest of the body, when cut into, had the appearance and consistence of hard, discolored wax. One leg was absent, having, probably, been separated by the weight of the mud when the body was pulled up by the dredger.

AMPUTATION OF THE PENIS BY GALVANO-CAUTERY.—Dr. A. Amussat reports a case of amputation of the penis for an epithelioma involving the whole of the glans and a portion of the body of the penis. The operation was done by seizing the penis, just behind the affected portion, in a loop of platinum wire, which was then attached to a battery and tightened very slowly in order to prevent hemorrhage. No accident occurred, a sound was left in the urethra, and in six weeks the wound had completely cicatrized, and the patient made a good recovery.

The next time he has a similar case Dr. Amussat proposes to make use of the elastic bandage for the purpose of compression, if possible, in order to be able to operate more rapidly, without danger of hemorrhage.—*Journal de Médecine et de Chirurgie Pratiques*, vol. xlv., p. 64, 1874.

CATHETERIZATION OF THE LARYNX IN CROUP AND DIPHTHERIA.—Huettner, of Vienna, regards the apparatus of Weinlechner as the best that has been devised for catheterizing the larynx. The description of the apparatus and the method of employing it are given in the *Jahrbuch f. Kinderheilkde*, for 1870. It consists of a hard rubber tube and a peculiar wedge, which keeps the jaws of the patient apart during the course of the operation. The following are some of

the statements that are made in regard to the advantages and disadvantages of this method of treatment. In introducing either a catheter or tube into the larynx, conditions may arise that will cause asphyxia in the child, either from lack of suitable assistance on the part of the operator, or from the detachment of portions of the false membrane which may then form obstructions in the trachea or bronchi. This latter accident has occurred twice under his own observation. It is almost impossible to avoid wounding the mucous membrane of the mouth or throat, and even slight wounds may cause hæmorrhage, and may even be the seat of fresh diphtheritic exudations. The effect of the operation is but temporary, as the relief it gives lasts only a few hours, and it requires a number of skilled assistants if success is to be expected; experience has shown that the operation should be performed but once, and then only to gain time. It can never be regarded as a substitute for tracheotomy. The author in making these statements does not mean to decry the utility of this operation in other affections of the larynx. — *Jahrb. f. Kinderhkd.*, Sept., 1874.

Reports of Societies.

NEW YORK COUNTY MEDICAL SOCIETY.

Adjourned Meeting, Jan. 12, 1875.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

THE paper for the evening was read by Dr. George M. Beard, upon "The Relation of the Medical Profession to the Delusions of

SPIRITUALISM, ANIMAL MAGNETISM, CLAIRVOYANCE, MIND-READING, ETC.—HOW THESE SHOULD BE DETECTED AND EXPOSED."

The doctor, in the first place, gave a brief sketch of the history of animal magnetism in Germany, France, England and America. He showed how the hypothesis of a magnetic fluid, first started by Mesmer, had been disproved three times over, by careful investigations of very able men, committees of the French Academy. In England, the hypothesis was disproved by the careful experiments of Mr. Wakley and others. In America, the hypothesis has also been disproved by a number of experimenters. The Fox girls, who started the rapping excitement, were exposed by a committee composed of Dr. Austin Flint, Jr., Dr. Charles A. Lee, and Dr. C. B. Coventry, then members of the Faculty of the University of Buffalo.

Trance was described as a passive state, in which the will, partially or wholly, loses control.

The symptom of sleep is only one of very many of the symptoms that belong to the trance state. All persons are liable, under certain circumstances, to go into certain stages of trance. Trance is, in short, the *involuntary* side of human life. When under any circumstances the *involuntary*, or automatic part of a man, predominates over the voluntary part, then there is a state of trance. We may enter into this state through any of the emotions, such as fear, anger, love, joy, reverence, expectation, wonder; or through the influence of alcohol, opium, chloroform, nitrous oxide, etc., or anything which causes the will to be divorced from the mind. The common custom of making passes or manipulations on a subject is only one of many ways by which a patient can be put into a state of trance. In these cases it is the emotion of expectation or reverence or wonder that causes the subject to go into the trance, and not any force of magnetism which comes from the operator. The operator may be in the next room, far away; or many

can go into the trance of themselves alone at any time. A case of this kind is now under the doctor's observation. The leading symptoms of trance vary much in different persons, and may be embraced under the following heads.

- (1.) Closing of the eyes, and fixed condition.
- (2.) Flushing of the face and eyes, and cold perspiration.
- (3.) Hard breathing, rapid pulse, with sense of oppression.
- (4.) Coldness of extremities.
- (5.) Mild or violent involuntary muscular motion.
- (6.) Involuntary mental action, with exaltation of the faculties.
- (7.) Great exaltation or depression of the general and special sensation.
- (8.) Nameless and numberless hysterical symptoms.
- (9.) Profound and protracted sleep.

We can go into a trance through various pathological states, as hysteria and insanity; or through common sleep, somnambulism, ecstasy, catalepsy, which are all manifestations of a trance or automatic state.

All persons are liable to go into the trance state, under certain conditions, even the strongest minded. There are all degrees of trance, from the simple absent-mindedness of the scholar to the profound and protracted sleep of the hysterical girl, or those who claim to sleep under the influence of some extra-mundane power.

A person in a trance, with the hands upon a table, may, by *involuntary* muscular motion, make it strike, rap, and move about. With his hands upon a planchette, or holding a pencil over a piece of paper, he may write, through involuntary muscular action, thoughts, words, and phrases, and even languages which have been long forgotten. He wonders where they come from; but upon close study, you will find that they all come from past experience, and have been locked up within the cerebral cells. In a trance there is a very great exaltation of the faculties; but in no stage of trance is there a transference of faculties, or are new faculties given, differing in kind from those present in the individual when not in a state of trance.

Spiritualism is all trance and trickery, with a vast excess of trickery.

If the trance is well understood by the medical profession, the exposure of the trickery will be very easy.

The hypothesis of animal magnetism should be driven from the medical profession, for it has no basis whatever. There is animal electricity, but electricity and nerve force are now known to be identical.

The phenomena commonly *attributed* to animal magnetism are really the phenomena of trance.

Clairvoyance is all guess work and trickery. No human being has ever, in trance or out of it, in health or disease, had the power to read through opaque objects, or with the pit of the stomach, or to cerebrate at their fingers' ends.

The mind-reading of Brown is explained entirely by *involuntary* muscular action, or movements on the part of the person with whom he operates. It is very difficult, and for many impossible, to look at any object, and centre their mind upon it when near, without giving some impulse or muscular movement, *involuntary*, towards it; and, availing himself of this fact, which the profession have ignored, Brown has performed brilliant and surprising trickery.

The leading thoughts in this subject which ought to be kept before the professional mind are these:

- (1.) These illusions can only be studied with success by experts, and as they are medical illusions, the experts ought to come from the medical profession.

It is *our* business and not the business of any one else; and to chemists and physicists, and natural philosophers, and editors and statesmen, and especially lawyers and judges, we should say, "Stand aside; this is our department; we alone are competent to study it and solve the problems, and you must come to us for information."

One of the best evidences that a man is becoming expert in the study of these things is that he does *not* trust his senses.

(2.) In this, as in all branches of science, *human testimony* as such is worth nothing, and should be ruled out without examination.

In all other important departments we follow experts, and pay no heed to the opinions or prejudices or statements of others, and we must do the same here.

(3.) In proportion as medical men become experts in this special branch of inquiry will they come to know that all the performances of clairvoyants, mind-readers, mesmerizers, etc., can be explained by laws already known to experts, and by trickery; and that there is about them no mystery whatever.

(4.) The prime requisite for success in studying those who profess to have this power is to recognize the fact that we are the experimenters, and not they; and then they may be deceived at every point. We must treat these pretenders like animals in the laboratory.

One prominent reason why those who visit the seances give absurd accounts of what they see is because they are themselves in a trance through reverence of wonder, and see anything they are told to see. Hence their statements are worth nothing.

In conclusion the doctor stated that, since the exposure of various mediums, all the prominent mediums in the country have been exposed, some of them over and over again, and that there was no large city in this country where mediums dared to hold public seances; that there was a gradual improvement in society in that respect; that there never was a time in the history of civilization, in proportion to the population, when there was so little spiritualism as now. The present time, therefore is particularly auspicious for the medical profession to step in and study the subject from a purely scientific basis. If they do so, the result may be that clairvoyance, mind-reading, animal magnetism, psychic force, second-sight, spiritualism, and all the sisterhood of superstition, will be driven back to join their great progenitor witchcraft, and return to plague civilization no more forever.

Dr. J. C. Peters remarked at some length upon the trickery of so-called spiritual manifestations and mind-reading, and in conclusion presented the following resolution:

Resolved, That a committee of five be appointed by the chair to consider, and at their convenience report upon the following questions:

1st. Is the state or condition of mind known generally as the mesmeric state a reality or a deception?

2d. If it is a real physiological state, what are the conditions necessary to its production, and what the phenomena attending it?

3d. Is it a state to which one mind can subject another, or does it depend upon some conditions voluntarily submitted to by the individual?

4th. Is it possible while in this so-called mesmeric trance, or at any other time, or in any other condition known to man in his mundane experience, for one person to divine what is passing in the mind of another, except through the medium of signs?

5th. Is there any such faculty known to our race as perceiving by some mysterious second-sight what is

transpiring in places far beyond the reach of ordinary human vision, or what is written on paper when an opaque object lies between it and the person attempting to read?

6th. Is there any evidence that the well-known law of gravitation is ever overcome by a force hitherto unrecognized by scientists?

The resolution was adopted, and the following gentlemen named as the committee: Dr. Ellsworth Elliott, Dr. J. C. Peters, Dr. Fordyce Barker, Dr. Austin Flint, Sr., Dr. A. B. Crosby.

The society then adjourned.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from January 10th to January 16th, 1875.

CRONKHITE, H. M., Assistant Surgeon.—Assigned to temporary duty at Fort Yuma, Cal., and, when relieved by Assistant Surgeon Loring, assigned to duty as Post Surgeon at Camp Verde, A. T. [S. O. 113, Department of Arizona, Dec. 26, 1874.

ROSE, Geo. S., Assistant Surgeon.—When relieved by Assistant Surgeon Cronkhite, to comply with S. O. 233, C. S., War Department. S. O. 113, C. S., Department of Arizona.

LORING, L. Y., Assistant Surgeon.—Assigned to duty at Fort Yuma, Cal. S. O. 111, Department of Arizona, Dec. 21, 1874.

Medical Items and News.

NEW YORK EASTERN DISPENSARY.—At the Meeting of the Board of Trustees, held for organization, January 12th, 1875, the following officers were elected:—William Dennistonn, President; John T. Willetts, Vice-President; Robert R. Crosby, Treasurer; Russell Raymond, Secretary.

NEW YORK PATHOLOGICAL SOCIETY.—At the Annual Meeting of this Society, held January 13th, 1875, the following officers were elected:—Dr. Francis Delafield, President; Dr. E. G. Janeway, Vice-President; Dr. George F. Shady, Secretary; Dr. John H. Hinton, Treasurer, and Dr. J. C. Peters, Editor of *The Transactions*.

Committee on Admissions:—Drs. J. C. Peters, S. Caro, R. Newman, F. V. White, and J. H. Hinton.

Committee on Publication.—Drs. E. Mason, Drake, Newman, and Watts.

THE TWENTIETH ANNUAL CHARITY BALL in aid of the Nursery and Child's Hospital will take place at the Academy of Music on Thursday evening, Feb. 4th, under the usual management.

ALUMNI OF ALBANY MEDICAL COLLEGE.—At the second annual meeting of this Association, held at Albany on the 22d of December, the following officers were elected for the coming year:

President, Dr. John Buch ('41), Michigan. *Vice-Presidents*, Drs. Mon. D. Hall ('41), New York; B. A. Mynderse ('53), New York; Alex. Shilard ('53), New York; Sol. Van Etten ('53), New York; Chas. L. Spencer ('53), Massachusetts. *Secretary*, Dr. Willis G. Tucker ('70), New York. *Treasurer*, Dr. G. L. Ullman ('71), New York. *Executive Committee*, Drs. H. D. Didima ('46), William S. Young ('41), Jos. H. Sloon ('49), Jos. S. Baily ('53), M. H. Burton ('53), John H. Hill ('53), Charles H. Barbeck ('59), N. P. Ten Eyck ('66), J. H. Blatzer ('72), Oscar Myers ('73).

PHYSICIANS ACCUSED OF ROBBING GRAVES.—Some excitement has been caused in Terre Haute, Ind., by the arrest of Dr. W. H. Myers, a prominent physician, Dr. N. Myers and Dr. H. V. Werengen, on the charge of robbing a cemetery at Van Wert, Ohio, in December last, of the body of Carl Wolf, a German emigrant, who committed suicide. The arrests were made by Sheriff Billman, of Van Wert, on a requisition from Gov. Hendricks. The physicians were taken before Judge Lowry and discharged on account of a technical flaw in the warrant. It is said that they will be rearrested as soon as a new warrant can be obtained.

AN ANONYMOUS BENEFACTOR.—For several years past some unknown person has been in the habit of sending checks for £1,000, at intervals, to the several charitable institutions in London, and all efforts to discover who it was failed. The *John Bull* now says that it was a Mr. Attwood, who died recently near Cheshunt. He was above eighty years old, and a bachelor; rich, but living very quietly. His books show that he gave away £350,000 by these checks—£45,000 within the last year. He has left more than a million sterling and no will. A thousand pound note was found lying about the room, as if it had been waste paper.

AMERICAN MICROSCOPICAL SOCIETY.—At the annual meeting of the American Microscopical Society the following officers were appointed for the ensuing year: President, John B. Rich, M. D.; Vice President, W. H. Atkinson, M. D.; Secretary, C. F. Cox; Treasurer, Prof. T. L. Orenieu; Curator, William Dean.

SCARLET FEVER IN BUFFALO.—The *Buffalo Commercial Advertiser* says that scarlet fever has prevailed in that city to an extent greater than ever before, and that the number of deaths therefrom—principally among children—has been very large. The total number of deaths from this disease during the year 1874, as reported by the Health Physician, Dr. O'Brien, was 626.

THE SOUTHERN DENTAL ASSOCIATION will hold its next annual meeting at Memphis, Tenn., on the 9th of February.

THE NORTHERN DISPENSARY.—The Board of Trustees of the Northern Dispensary last evening elected the following officers for the ensuing year: President, Wm. K. Thorn; First Vice-President, John W. Quincey; Second Vice-President, John H. Mortimer; Third Vice-President, J. Harsen Rhoades; Secretary, John Lawrence; Treasurer, George C. Wetmore; Counsellor, Henry A. Taiter; Finance Committee: Edward Scheil, W. H. Braman, C. M. Earle, W. E. Lawrence and A. G. Bogart.

POISONING BY BELLADONNA.—A Mrs. Susanna Bowling died at Baltimore recently from the effect of a dose of belladonna which had been purchased from a druggist for syrup of senna.

METROPOLITAN THROAT HOSPITAL.—At the annual meeting of the Trustees of this Dispensary, at No 17 Stuyvesant street, a full Board of Trustees was elected. During the past year the visits made to the hospital by patients suffering from affections of the throat and nose has been 3,408, and thirty-four surgical operations have been performed.

A PHYSICIAN AT NORTH GUILFORD, CONN., recently attempted to collect a bill of \$50 for professional services, when it was offset by a formidable bill for dinners, horse baitings, presents of milk, fruit and vegetables, all of which had been tendered ostensibly out of good will. Strange to say, the patient's

offset was held valid in a New Haven Court, and the doctor had to pay \$7 to get square.

THE AMERICAN METEOROLOGICAL SOCIETY, at its annual meeting, held at the Cooper Institute in this city on the 28th of last month, adopted the following resolutions:

Resolved, That this society highly approves of the plan which has been set on foot among the members of scientific professions in the United States to secure a general consent to the adoption of the metric measures and weights in their professional practice after July 4th, 1876.

Resolved, That the members of this society will, as far as they may be able, employ their personal influence in aid of the plan above mentioned.

Resolved, That a committee be appointed to recommend the erection in the various State capitals of a standard yard and metre, to be provided by the Bureau of Weights and Measures of the United States.

THE OLIVE CROP.—Olive oil is produced in large quantities in Tunis. The olive crop has been so abundant during the past year that as many as 3,472 tons, of the value of \$629,465, have been shipped to Great Britain, France and Italy.

PERMANENCE OF VITAL POWER.—In clearing away the refuse from the ancient silver mines of Larium, in Greece, a large number of seeds of a papaveracea of the *Glaucium* genus were found, which must have been buried there for at least fifteen hundred years. Exposed to the beneficent influence of the sun's rays, they rapidly took root, flourished, budded and blossomed, their yellow corollas being beautiful in the extreme. This interesting flower, unknown to modern science, is particularly and frequently described in the writings of Pliny and Dioscorides, and is thus again resuscitated, after having disappeared from the surface of the globe for more than fifteen centuries.

DR. T. H. HOLGATE.—Among the numerous sufferers from falls upon slippery pavements, is Dr. T. H. Holgate, of 263 W. 15th street, who, on the night of the 12th instant, had a fracture of the upper extremity of the femur.

ALEXANDER S. DOHERTY, A.M., M.D.—Dr. Alexander S. Doherty, lately residing at 138 E. 29th street, died on the morning of January 19th instant, of double pneumonia, aged twenty-seven years. He was the second son of William Doherty, and was a native of St. John, N. B. He was educated at St. John's College, Fordham, and was a student in medicine of Prof. James R. Wood. He received the degree of M.D. from Bellevue Hospital Medical College in 1869, and held the following appointments in the institutions in this city:—Assistant Physician, Nursery Hospital, Raudall's Island; Examining Physician, Department of Public Charities and Correction; and Resident Physician, New York City Inebriate Asylum. At the time of his sickness he was engaged in private practice.

THE BLEACHING OF BONES AND IVORY has been rapidly and successfully carried out at the museum of the *Jardin des Plantes*, by immersing the articles in spirits of turpentine, taking care that they are kept a short distance from the bottom. When treated in this manner and exposed to sunlight, a few days, it is said, suffice to free bones from fat and disagreeable odor, and render them beautifully white. Woods of different kinds may also be bleached in this manner. The necessity of keeping the articles from touching the bottom of the vessel is on account of the formation of an acid substance which collects at the bottom of this fluid, and is capable of attacking the substances being bleached.

A NEW CAUSE FOR BLUE (LEAD) LINE ON GUMS.—A writer in the London *Lancet* asserts that the constant use of powdered charcoal as a dentifrice will produce a blue line on the gums, closely simulating that of lead-poisoning.

DIPHTHERIA.—The Board of Health of this city have appointed Drs. Edward Curtis and Thomas E. Satterthwaite, of this city, to investigate the subject of Diphtheria, with a view to determine more nearly, if possible, the character of the disease and the best means for contending with it.

A HANDSOME MEDICAL FEE.—Dr. Waldau, of Berlin, assistant of the late Von Graefe, received 25,000 thalers from the banker Bleichroeder, for a cataract operation.

BROMINE is largely manufactured in Western Virginia. One hundred and thirty thousand pounds were produced in the Ohio and Kanawha valleys in the year 1873.

SMALL-POX AMONG THE KALMUCK TARTARS.—Nowhere, says the *Golos*, does variola make such ravages as among the Tartars. When the disease bursts in the midst of a family all the ties of blood and friendship are broken; often the Tatar, quitting his mother, wife, and children, mounts on horseback and flees his country. When the plague descends on a tent in winter, those it attacks are almost infallibly lost, abandoned as they are under a light tent to a cold of more than 25° below zero. Sometimes only fifteen days suffice to destroy a whole family. The only remedy they use is hot milk, diluted with water; the sole preservative is brandy.

The Tartars almost never bury their dead; they drag them to some distance from the camp, and leave them on the sand. It is not rare to see a hungry dog carry off a leg, a foot, or an arm, to the tents, and devour it in the sight of the relatives. There are no doctors nor hospitals. There is merely to be mentioned the village of Jardik, on the postal route, with its miserable hospital of fifteen beds. There is, indeed, a medical man attached to the administration of the Kalmucks, far from the centre of the Steppes, at Astrakhan; but this doctor's time is always occupied by violent deaths; he has not a moment left for ordinary diseases.

DETERMINATION OF SEX IN UTERO.—"We have been informed, on good authority, that the sex of five children in this city was lately determined before birth, according to the frequency of pulsations of the fetal heart, which are said to be more frequent in females. The children were all pronounced girls, but they all turned out to be boys. There must be something in the rule."—*Pacific Jour.*, Sept.

DESERTS AS HEALTH RESORTS.—At a recent meeting of the Munich Academy of Science, Professor Zittel read a paper detailing the results of observations made by him with regard to the air of the Lybian desert during the months of January, February, March, and April, 1874, tending to prove that the air of this desert contains a very much larger amount of ozone than that of the oases, or the Nile valley. The belief that the desert air is beneficial to invalids, especially those suffering from pulmonary complaints, is of ancient origin, and, in accordance with this idea, the Kabin has recently decided to repair to Helmau, in the so-called Eastern or Arabian desert.

A NOVEL REVENUE QUESTION.—A curious question has lately arisen in one of the Swiss custom-houses in connection with the water from the miraculous fountain

of Lourdes. The water of this holy spring is exported largely abroad, for the benefit of the faithful, and a consignment having been offered at the Basle custom-house the officers demanded the duty on medicaments. To this it was replied that the water was not a medicament in the usual sense, but only water to which the mystical power of faith alone gives medical properties. The logic of the reply is unanswerable—that the liquid was sent as a medicament to Switzerland, and was therefore subject to duty as such. With the question of its intrinsic value, the department had nothing to do, any more than with that of any other empirical remedy.

THE BOARD OF HEALTH, in order to bring its expenditure within the limit of the appropriation for the coming year, has been obliged to reduce the salaries of the Sanitary Superintendent, Dr. W. De F. Day; the Secretary, Col. E. Clark and the Registrar of Vital Statistics Dr. E. Harris; and to dispense with the services of several inspectors, assistant inspectors and members of the vaccinating corps. The salaries of the sanitary inspectors have also been reduced from \$2,000 to \$1,800.

A NEW MALADY AMONG HORSES.—The *Detroit Post* of January 15th says a malady differing in many respects from the "Epizootic" is prevailing among horses in that city. The horse becomes weak in the legs, staggering as he walks, refuses to eat, the eye loses its lustre, the hair its glossiness, the head hangs downward and is apparently raised with considerable difficulty, and the breathing is hard and stertorous. There is, however, no swelling in the throat nor copious yellowish discharge from the nostrils, as in case of epizootic. The physicians who have investigated it generally agree that this disease is a species of influenza, which soon develops into lung fever.

SNEAK THIEVES.—Several thieves of both sexes are engaged in visiting the offices of physicians in this city, and we hear of numerous losses of instruments, books, clothing, etc. A woman named Helen Miller was recently arrested on a charge of grand larceny, preferred by Dr. Francis V. White, of No. 222 East Twenty-first street. She was taken before Superintendent Walling and was accused of having stolen surgical instruments valued at \$80. It was afterward stated by Dr. David M. Cory, of No. 56 West Twenty-fourth street, that the prisoner answered the description of the person who robbed his office some time ago of a considerable amount of property. It is said by the police that she is an old offender. The latest thefts which have come to our notice have been in the nineteenth ward.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, January 25.—Medical Society of the County of New York. Discussion of Dr. Jacobi's Paper on Diphtheria, after which Dr. Simon Fitch will show an Improved Form of Trocar, with especial reference to Ovariotomy and Aspiration.

Tuesday, January 26.—American Microscopical Society. Yorkville Medical Association.

Wednesday, January 27.—New York Pathological Society.

Thursday, January 28.—New York Medico-Legal Society, Brooklyn Pathological Society, Jersey City Pathological Society.

Friday, January 29.—Medical Library and Journal Association. "Report on the Progress of Surgery." Dr. S. B. Ward.

Original Lectures.

ON THE SYMPTOMS

OF THE

FIRST STAGE OF MORBUS COXARIUS.

By LEWIS A. SAYRE, M.D.,

PROF. ORTHOPEDIC AND CLINICAL SURGERY IN THE BELLEVUE
HOSPITAL MEDICAL COLLEGE.

[Reported for THE MEDICAL RECORD.]

GENTLEMEN:—The symptoms of morbus coxarius vary according to the stage in which the disease presents itself.

Ordinarily these stages are described :

- I. The stage of inflammation or of limited motion, before the occurrence of effusion.
- II. The stage of "apparent lengthening," or of effusion; the capsule of the joint remaining entire.
- III. The stage of "shortening," or of ruptured capsule.

For the second and third stages, I prefer to use the terms *effusion* and *rupture*, rather than "apparent lengthening" and "shortening," as the latter describe only a single feature of the deformity present in each stage, while the former designate an essential pathological change which underlies a group of symptoms. What, then, are the symptoms of the *first stage*?

The symptoms of this stage are sometimes exceedingly obscure, particularly if the inflammation be of a low grade or of the chronic character generally found in those of a strumous diathesis. The first thing that attracts the attention of the patient or his friends is generally a stiffness about the joint and a limping gait, for which, perhaps, they will be unable to assign a cause. The real cause (commonly traumatic) has been forgotten in consequence of the slow and insidious approach of the disease. This stiffness of the joint is commonly noticed first in the morning when the patient gets up. After he has been about for awhile he becomes limbered up and can travel without stiffness or appreciable limp. But, even then, when he stops walking or running he will, within a minute or two, invariably stand upon the sound leg, apparently for the purpose of relieving the affected one.

Now, even at this early stage of the disease, if the patient is brought to the surgeon, a careful examination will reveal the following condition of things.

It is to be noticed, however, that, no deformity of which you are certain can be detected at this stage unless the patient is completely stripped of clothing from the waist down, and then placed in a proper position.

When the patient has been stripped, place him first in the standing position, and directly in front of you with his back towards you.

The light should fall directly upon his back, in order that you may not be deceived with regard to details of contour by any shadows. Your examination should not be hurried, for you wish to detect the disease in its very incipency, in its most shadowy form, and that may require a little time. After watching the patient a short time you will notice that he makes a solid column of the sound leg for the purpose of receiving concussion and bearing the weight of the body, and also carefully avoid all concussion of the suspected limb. You will further notice that the suspected limb has a tendency to slight abduction and slight flexion

at the knee and hip, but the feet stand parallel with each other. The natis upon the side of the lameness drops a trifle; is somewhat flattened, and the gluteo-femoral crease is lower and shallower than upon the healthy side.

This drooping of the natis is due to relaxation and gravitation of the glutal muscles while the weight of the body is thrown upon the sound leg; for the same thing obtains if the knee-joint be affected or a perfectly sound person throws his weight upon one leg.

This symptom, then, has a diagnostic value only so far as this—it indicates to us that from some cause the patient rests the weight of the body chiefly or entirely upon one limb. But from this peculiar favoring of the affected side we can often detect the incipient disease, even before a limp has been noticed. Next you will determine whether there is present any rigidity of the psoas magnus, iliacus internus or adductor muscles of the thigh; for rigidity of these muscles appears very early in the disease, and if none of them give resistance to the full performance of their normal functions, it is fair to assume that the joint is not diseased.

To make an examination for this purpose it is necessary to lay the patient upon his back upon a firm flat surface like a table or floor. This examination *must* be made upon a *solid*, flat surface. A bed or sofa or lounge, therefore, will not answer; for the inequalities of either will adapt themselves to the curvatures of the spine, thereby preventing you from detecting the deformity of this early period of the disease.

Before proceeding farther it is necessary to place the patient in such a position as will furnish a proper starting-point from which you may conduct your examination. Such a position is one in which the pelvis and trunk bear a normal relation to each other and is described as follows:

When the pelvis and trunk bear a normal relation to each other, a line drawn from the centre of the sternum over the umbilicus to the centre of the symphysis pubis will be crossed at right-angles by a line drawn from the anterior superior spinous process of one ilium to the other. With the pelvis and trunk in this position the thighs can be sufficiently elevated to bring the spinous process in contact with the table throughout the entire length of the spine. Ordinarily there is a slight curve of the spine at the lumbosacral junction when the patient is placed upon the back, but by elevating the thighs in the manner described that curve will be entirely obliterated and the spine brought straight. Now we have some standard by which to be governed.

With the trunk and pelvis in this position, then, and the spinous processes upon the table, if there is no rigidity of the psoas magnus or iliacus internus muscles, the thigh can be so extended as to bring the popliteal space in contact with the table without disturbing either. But the pelvis or spine, if any contraction is present, and the thigh is brought down in the manner indicated, when it is perhaps one-third or one-half extended, it meets with resistance and the anterior superior spinous of the ilium upon the side of the contraction drops below the other in consequence of a tilting of the pelvis. If, however, the pelvis is held firmly, while the thigh is brought down, after the psoas magnus and iliacus internus muscles have stretched as far as possible, the spine at once arches from the table or floor upon which the examination is made. This arching of the spine in many cases at this early period in the disease is so *slight* that it would be *entirely* overlooked were the examination made upon other than a *solid* flat surface.

Complete flexion at this period of the disease is also

impossible. The well limb can be flexed so as to bring the knee in contact with the chest; but the diseased limb can probably be flexed only at right angle or a little more than right angle with the body, before the pelvis will be raised. The moment the pelvis begins to raise that moment you have reached the limit of flexion.

Adduction is very limited indeed. The diseased limb cannot be crossed over the opposite limb, and even by the time it has reached the median line the pelvis begins to move, showing that you have reached the extreme limit of adduction.

Abduction, particularly if the limb is slightly flexed and at the same time rotated outwards, can be carried to an extent somewhat greater than adduction, but *not to full abduction*, before the pelvis will begin to move, showing that muscular rigidity is present.

Now, in whatever position the affected limb must be held in order to bring the pelvis and trunk into a normal relation with each other, that is, so the two lines mentioned shall cross each other at right angles and the spine be upon the table or floor. Such position indicates the *deformity* present at the time of making the examination, and indicates the stage to which the disease has arrived.

In the first stage, therefore, as can be seen in these cases before you, the thigh is flexed very slightly upon the pelvis, and very slightly abducted; and, the pelvis being held *perfectly still*, very limited motion can be made at the joint, when slight extension is made upon the limb. Attempts to *extend* the limb beyond a certain point, as you now observe, tilts the pelvis; flexion beyond a certain point—in this case not quite to a right angle with the body, in other cases it may be to more than a right angle—tilts the pelvis; whereas upon the well limb extension can be made complete, and flexion complete, so as to bring the knee against the trunk.

Abduction, adduction and rotation are also limited, as you observe, and when carried beyond a certain point the pelvis at once moves with the limb, giving the boy an appearance as if complete ankylosis had taken place at the hip joint. But there is no real ankylosis present in this stage of the disease. There is ankylosis, perfect and complete to all *appearance*, but it is due simply to muscular rigidity. For by placing the hand upon the pelvis, and making a gentle extension upon the limb for a few seconds in the *line of the deformity*, motion can be made at the joint without causing pain; but the moment extension is removed limited motion causes pain, the muscles suddenly become rigid, and the child can be rolled around like a *solid stick*.

If the disease, however, has passed beyond the first stage, and effusion has taken place, then abduction is much more marked, and flexion is much stronger than the first stage, but the *peculiar* feature of the deformity then is *eversion* or *rotation of the foot outward*. These symptoms will be more fully considered when we come to speak of the symptoms of the *second* stage.

Another symptom of the first stage that is too often overlooked is atrophy of the thigh or entire limb. Therefore always compare the limbs by actual measurement, for the rapidity with which atrophy takes place in some cases is really surprising, and is due to the direct influence of immobility of the joint. The symptoms, as we have studied them thus far, all point to one thing, namely, fixation of the joint, restraining motion as much as possible. This will occur without the slightest recognition of pain on the part of the patient, and is due to what Mr. Barwell terms "joint sense."

The symptoms of which the *patient* will complain are tenderness and pain. Tenderness is usually well

marked; although sometimes it is necessary to make a thorough examination of the joint before its presence can be detected. The disease may be situated at any part of the joint surface, and we ought, before denying the existence of tenderness, to make pressure upon every part of the head of the femur or acetabulum that could have been involved in the original injury.

This can be done by placing the thigh in all possible positions, and at the same time make pressure upon the head of the bone and the acetabulum by crowding the articular surfaces together.

In addition, pressure should be made upon the great trochanter in order to bring the head of the femur and acetabulum in contact from that direction.

Again, holding the knee with one hand and fixing the pelvis with the other, press the thigh bone upwards. This manœuvre generally causes pain, which can be detected in the patient's face, even when he denies he feels it. If the manœuvre *does* cause pain, then please observe whether or not extension relieves it. To make your examination doubly sure, if tenderness has not already been detected, sweep with the thigh its largest possible circle, by which means the head of the bone cannot possibly escape being brought in contact with every part of the acetabulum. *Pain* may or may not have been experienced during the *first* stage.

In those cases when the disease manifests itself immediately after the injury—which cases are probably either synovitis or periostitis of the great trochanter—the pain is also immediate and constant, and frequently excruciating.

In other cases, when probably the seat of the disease is in the articular lamella—either beneath the articular cartilage of the head of the bone or the acetabulum—pain is developed late in the first, or even not until the second stage.

This pain may be referred more or less definitely to the hip-joint and its surrounding tissues, or it may be so entirely located in the knee as sometimes to completely mislead the surgeon in his diagnosis. I have many times seen the knee blistered and treated for months, when there was no disease whatever at that joint, it being merely affected by the disease in the hip.

Mr. Barwell explains the knee-pain as follows: It is produced (1) by direct irritation of the nerves passing in close contiguity to the joint. These are the obturator nerves, the sciatic, the gluteal and perhaps the anterior crural. It is produced (2) in consequence of an obscure sympathy between the two ends of the bone, or even direct propagation of the inflammation from one to the other; and (3) by spasm of certain muscles.

Such, gentlemen, are the symptoms by which you are to recognize hip-joint disease in the *first* stage.

No one of them is entirely diagnostic. The certainty of the diagnosis depends upon a careful consideration of *all* the symptoms described.

We have thus dwelt upon them at some length, because many of them differ from those of more advanced stages only in degree, consequently require only one description; but more especially because it is in this stage that diagnosis is most difficult and important. In the later stages, it is almost impossible not to recognize the disease, but the patient has then endured great suffering, and perhaps great mischief may have resulted, which might have been easily *prevented* had the true nature of the disease been early recognized.

THE ARMY MEDICAL STAFF RANK Bill has been favorably reported by the House Military Committee, and it will probably come before the House this coming week.

A CLINICAL LECTURE ON TYPHOID FEVER AND BRONCHO-PNEUMONIA.

DELIVERED AT BELLEVUE HOSPITAL,

By FRANCIS DELAFIELD, M.D.,

ATTENDING PHYSICIAN.

CASE I.

GENTLEMEN:—I will ask your attention this morning to these diseased intestines and lungs. They were taken from the body of a young woman who died in this hospital. Her stay in the hospital was short, her previous history was obscure, and her symptoms were perplexing, so that I will not occupy your time with the consideration of the clinical aspect of the case.

First, then, let us examine the intestines. You will observe that in the lower part of the ileum there are a number of large and small ulcers, corresponding in their situation to the agminated and solitary glands. These ulcers have thick edges, their walls and floors look something like granulation tissue. In some of them we see yellowish sloughs of some size still adhering to the floors of the ulcers. If you turn over the intestines and look at their external surface, you will see in and beneath the peritoneal coat, corresponding to the position of the ulcers, a number of small, rounded grayish bodies.

Such ulcers are one of the characteristic lesions of typhoid fever. In typhoid fever we find an enlargement of the agminated and solitary follicles of the ileum. This enlargement is followed by degenerative and ulcerative changes. In mild cases we find only small ulcers, involving perhaps only portions of the agminated follicles. Such have been the lesions in all the cases of typhoid fever which I have seen this fall.

In severe cases, however, the follicles attain a greater degree of enlargement, and the new growth of cells infiltrates the adjacent portions of the intestine. Instead of ulcerating subsequently, large portions of the enlarged follicles die and form sloughs of considerable size. This is the condition of affairs in the intestines of this patient.

Now, let us look at the lungs taken from the same patient. They present us with a picture of acute broncho-pneumonia, such as we rarely see in the adult. Except for their size these lungs have exactly the appearance of the lungs of a child two years old with broncho-pneumonia. The bronchi are congested and lined with muco-pus. In the lung-tissue are numerous patches of hepatization, some red, some rather purple in color. In some of the lobules of red hepatization you will notice small grayish patches about the size of a pea. These correspond to small bronchi and zones of air-cells around them.

This condition of the lungs is one of the regular complications of typhoid fever. It is apt to be a very troublesome one. Not infrequently the lung lesions assume a chronic character, and the patient develops the symptoms of pulmonary phthisis.

These lungs, therefore, may serve to illustrate to you the form of broncho-pneumonia which may complicate typhoid fever, and may also serve as an example of the early stage of one of the varieties of pulmonary phthisis.

CASE II.

In this boy, gentlemen, you may observe the results of such changes in the lungs as you have just seen, if these changes persist and become chronic. The boy, is 15 years old. His father and mother died of

phthisis. He has been badly fed, badly clothed, and constantly exposed to cold and wet. For about three months he has had a cough. This cough has increased in frequency and severity, and is now attended with profuse muco-purulent expectoration. He is now feeble, emaciated, and has hectic fever with night-sweats.

If we examine his chest we find evidences of bronchitis over the whole of the right lung, together with consolidation of its upper portion.

If we could look at this boy's lung at this moment we would find just such changes as you have seen in the lungs from the typhoid fever patient—but farther advanced. The bronchitis is no longer acute—but chronic. The bronchial mucous membrane is trabeculated and the fibrous coat of the bronchi is thickened. The hepatized lobules of lung tissue are no longer only red, but some are gray and some are cheesy. There is not only an inflammatory exudation filling the air-cells, but a new growth of fibro-cellular tissue between them.

What is the prognosis in this case, and what should be the treatment?

The *Prognosis* is not very bad. The right lung only is involved, and the process does not seem to have invaded a very large portion of that.

Of course, his recovery will depend very much upon the condition in which he is placed. In the hospital, in some respects he is well off, while in other respects he is unfavorably situated with regard to recovery.

With regard to treatment in these cases, it is always to be directed both towards the lesion of the lungs, and towards the general condition of the patient.

The direct treatment of the lungs consists in making certain applications to the chest-walls. Of the various applications employed, I am very partial to dry cups, especially in the earliest stages. If we had seen this boy in the second or third week of his disease, we should have employed dry cups over the chest every day. Repeated cuppings, even now, will be very serviceable. These patients should not be cupped too hard. It is better, therefore, that you should apply the cups yourselves rather than rely upon professional nurses or cuppers. All you wish to do is to produce a free determination to the skin, without producing ecchymosis or making the skin sore. Used in this manner dry cups are useful, especially in the earlier stages; and even in the later stages are of positive benefit. It has seemed to me sometimes in adults, in cases of broncho-pneumonia in which apparently the disease was about to go on into chronic phthisis, that the disease has been cut short by the steady, persistent application of dry cups. The success attending the use of this remedy depends very much upon the attention you yourself give to its application. If you do not use cups, some other form of counter-irritation should be employed, such as blisters, iodine, croton oil, etc.

The treatment of the patient's general health is to be regulated a good deal by the condition of the stomach and bowels. If the appetite is good and the bowels regular, cod-liver oil will be of service. Sometimes great benefit will be derived from the use of the syrup of the lacto-phosphate of lime. This remedy is especially beneficial in the treatment of children.

Churchill's preparation of the hypophosphites is also valuable.

But these remedies are principally valuable in those cases in which the stomach and intestines are in good condition. If the stomach and intestines are not in good condition, the appetite poor and the bowels irregular.

you must turn your attention towards these before crowding tonics, cod-liver oil, and food. For the purpose of improving the condition in this respect we may resort to the use of remedies for the improvement of the appetite, such as the mineral acids, various preparations of iron, quinine, etc.; and sometimes these remedies can be used with very great benefit. Sometimes one article will do best, sometimes another.

If there is much vomiting, as not unfrequently there is, you will find that relief can be obtained sometimes by the use of a mineral acid and sometimes by the use of an alkali. Sometimes dilute hydrocyanic acid will be of benefit. With regard to cough, if it is not troublesome let it remain untreated. If sufficiently severe to prevent sleep, and to wear upon the patient, and perhaps to cause vomiting, something must be done towards affording relief. If the cough is very severe indeed, nothing will control it except preparations of opium; but, in the use of opium, get along with as little as possible. When less severe, sometimes hydrocyanic acid will check the cough; and there are several other remedies that may be employed for the same purpose. In some cases, sanguinaria is a remedy of considerable value. It is hard to be certain as to the exact effect of this remedy; but it has appeared to me that in a case in which the bronchitis predominates over the pneumonia, the sanguinaria is a remedy of considerable value in checking the cough.

The safest method of administration is to begin with five or ten drop doses of the tincture, and gradually increase to twenty or thirty drops every three or four hours. Vomiting may be produced if large doses are used at the outset.

In such cases as this, one of the best things that can be done is to remove the patient, if possible, to a better climate. For, there is here a reasonable chance for recovery, and a change of climate would be beneficial.

In those cases where the disease is very far advanced, and one or both lungs involved to a considerable extent, change of climate is hardly to be thought of.

A CASE OF ASPIRATION IN PERICARDITIS WITH EFFUSION.—The above operation was recently performed in Birmingham, England, on a youth aged twenty, suffering from dyspnoea, the result of effusion in the pericardium, occurring during an attack of acute rheumatism.

The needle was passed at a point in the intercostal space, between the fourth and fifth ribs, two inches to the left of the median line. Fourteen ounces of fluid, deeply tinged with blood, were withdrawn. Immediate relief from the dyspnoea ensued, no ill effects followed the operation, and within a month the patient was able to walk about the house. The case shows the ease and safety with which the operation may be performed, and also that no unfavorable import need be attached to a free admixture of blood with the fluid withdrawn.—*The Lancet*, December 19, 1874.

ASCARIDES TREATED BY ENEMATA OF COD-LIVER OIL.—Five tablespoonfuls of the pure oil were prescribed by Szerleki, as an enema, to be used twice daily. The effect of this treatment was primarily to bring away many living worms, and, after being continued for some days, to relieve the patient wholly of the itching and soreness in the perineum, and of the resulting fever, by which he had been very much reduced.—*Ally. Med. Cent. Zeit'g.*, June 20, 1874.

Original Communications.

POLYPUS OF THE UTERUS, TREATED BY THE INTERNAL ADMINISTRATION OF ERGOT.

By DANIEL F. COLLINS, M.D.,

NEW YORK.

Mrs. E. S., a short, thin woman, of sallow complexion, and the mother of four children, sent for me to attend her, as she said, for a "womb trouble." On calling, I found her exhausted from uterine hæmorrhage and in a very dangerous condition.

In answer to my questions, she stated that she was sick and in delicate health for the past six months, and had suffered a great deal from "flooding," and that these attacks generally came on every eight or ten days. But for the last two months she lost more or less blood all the time.

Having checked the hæmorrhage I left, promising to call the following day.

On calling next morning I found her free from any symptom of flooding, but in a very weak condition. On introducing my finger through the os uteri, I found at the upper and posterior portion of the organ a round substance or tumor about the size of a small orange; passing my finger around it I found it was impossible to pass even the point of my finger between the base of the tumor and the side of the womb, and that the tumor seemed to be closely attached to the wall of the uterus. The patient being very weak and nervous from loss of blood, I deferred further examination until next morning, which further examination satisfied my mind that it was impossible to remove the tumor in its present condition and relation to the uterine wall without a considerable and dangerous loss of blood, which, considering the weak and exhausted condition of my patient, I did not feel justified in risking.

After a consideration of the case, I decided on giving moderate doses of ergot in combination with a little opium, in order to bring on such contractions of the uterus as would separate the polypus or tumor from the uterine wall, sufficiently for me to either strangulate the tumor or remove by excision.

On paying my visit next morning, the patient complained of "bearing down pains," and said that she suffered as much as if she were in the beginning of labor.

On making an examination I at first found considerable difficulty in introducing my finger through the os, owing in the first place to the state of contraction the uterus was in, and secondly to the tumor pressing down from the fundus of the womb, and as if blocking up the passage.

On succeeding in introducing my finger, I found that the body of the tumor or polypus had entirely separated from the wall of the uterus, and was but now held by a small pedicle about three quarters of an inch in length, by a little less than half an inch in diameter.

After a careful examination I could find no trace of pulsation in the pedicle, but found it soft, and to the touch not unlike that of the umbilical cord.

Taking a gentle but firm hold of the polypus, I turned it round and round several times and then withdrew my hand.

After cautioning my patient against any unnecessary exertion, and telling her to send for me if there was any change in her condition, I left.

On the following morning I found on examination that the pedicle had softened a good deal owing to the twisting the previous day, and discovering no trace of pulsation in it I at once passed up a curved blunt-pointed scissors, and with one clip severed the connection between the polypus and the wall of the uterus. I immediately gave the patient a dose of ergot which brought on firm contractions in a short time. The polypus was expelled, the patient not having lost a teaspoonful of blood.

The polypus was of fibroid character and measured two and one half inches long by two and one quarter inches in diameter, and was hollow, containing a lot of grumous blood.

The patient rapidly recovered and is now strong and healthy, has had no hemorrhage since the removal of the polypus, and is quite free from "womb trouble."

Having examined several of the latest works on uterine diseases, I cannot find in any of them any allusion to the exhibition of ergot in cases similar to the above. That is, giving ergot as a means for separating, as far as its attachments will allow, the body of a tumor or polypus from the wall of the womb before removal.

Churchill, in his treatise on the diseases of women, says, in speaking of the treatment of "polypus of the uterus:" "In order to hasten the expulsion of the polypus through the os uteri, it will be advisable to give ergot; and more especially as, even if there be no polypus, its effects in restraining the hemorrhage will be beneficial. If the polypus appear and disappear, we may employ ergot, and at its reappearance fix it with Museux forceps and draw it down and tie it." In the above quotation, ergot is advised to be used simply to hasten the expulsion of the tumor, the forceps being recommended as a means of drawing the tumor down.

McClintock, in his work on the diseases of women, makes no mention of ergot as a means of lengthening the neck of a polypus before removal, or for separating the tumor as far as possible from the uterine wall.

Another question that presents itself in considering the above case is—In many of the cases that are treated as fibroid tumors of the uterus, in which the physician finds the tumor firmly and closely attached to the wall of the uterus, and almost imbedded in it: would not the careful use of ergot in many of these cases, change our diagnosis from that of fibroid tumor to simple polypus, and consequently alter our treatment in many cases, from giving temporary relief and using palliative measures, to a permanent cure by the removal of the morbid growth?

That the judicious use of ergot itself or in combination with opium will, in a large number of cases, materially help and simplify the operation of removal I have little doubt. It will do so by producing sufficient artificial contraction of the uterus to enable that organ to separate, as far as its attachments will permit, the morbid growth from its walls. In doing so, the danger of including a portion of the wall of the uterus is removed, or at least greatly lessened, and in many cases a dangerous hemorrhage avoided.

246 E. THIRTY-FOURTH ST., N. Y.

A MEXICAN MEDICAL JOURNAL.—"Repertorio Jaliscoense Medicina y Cirugía Practicas" is the title of a new semi-monthly medical journal which makes its appearance in Mexico under the editorial management of Señors Clement, J. Garcianiega, and N. Puga; being published in the city of Guadalajara, in the State of Jalisco.

A CASE OF POISONING BY STRYCHNIA,
SUCCESSFULLY TREATED WITH
CHLOROFORM AND CANNABIS INDICA.

By LAWRENCE JOHNSON, M. D.,

NEW YORK.

AT about 8 P.M., Sept. 29th, 1874, A. A. R., a healthy young man, aged twenty-two, with suicidal intent, swallowed five or six grains of strychnia in a glass of soda-water. He had obtained it of a druggist upon the pretence of wishing to poison rats; and the druggist informed us of the quantity furnished.

I was called to see him about fifteen or twenty minutes later; found him half-reclining upon a chair, being held in that position by a man on either side. He was in violent tetanic convulsions, every muscle seeming to participate, his face livid, and frothy saliva flowing from the mouth. I immediately sent for chloroform, which was procured in about five minutes, and having laid the patient upon the floor, proceeded at once to administer it to him by inhalation. He passed under the anæsthetic influence rapidly, and simultaneously his convulsions ceased.

About this time Drs. Wm. C. McFarland and T. L. Janeway arrived, and we consulted together. We concluded to continue the chloroform, allowing a brief respite now and then to note the effect of its suspension.

During one of these intervals shortly afterward, our patient opened his eyes and spoke, asking for drink, etc. Giving him water, he drank it, but with difficulty, the exertion bringing on a convulsion. With the idea of getting rid of any of the poison remaining in the stomach, we gave him two doses of sulphate of zinc, grs. xv. each, at within about ten minutes of each other. Shortly afterward he vomited freely, ejecting a large quantity of liquid, together with some undigested food. During the whole of this time every effort at swallowing was accompanied or followed by convulsions, as was nearly every voluntary movement, or even a current of air blowing over him, and consequently he was kept steadily under the influence of chloroform to a greater or less extent. At 10 P.M. the convulsions continuing whenever chloroform was suspended, we gave ʒi tr. cannabis indica, and ten minutes later another dose of like quantity. Soon afterward he vomited. Half an hour later another dose of ʒi was given, and two more at intervals of half an hour and one hour, all of which were retained. The convulsions meanwhile diminished in frequency and force, and chloroform was only resorted to when they occurred. After 11 o'clock convulsions seldom occurred spontaneously, for the most part being directly induced by voluntary movements upon his part or by his attendants accidentally touching him. At 1 A.M. we considered him out of danger and left him for the night.

He had but one convulsion after our departure—at 3 P.M., and at 9 A.M. we found him able to walk to his home, half a block distant.

How much of our success should be attributed to chloroform and how much to cannabis indica is of course a matter of conjecture. That sufficient strychnia had been absorbed to produce death I think the violence of the initiatory symptoms warrant us in assuming. Then chloroform in the first instance assuredly saved life. Yet inasmuch as there seemed no permanent improvement until cannabis indica was administered, while after that time the gain was rapid, I think the conclusion that its action was that of an un-

tidote a very reasonable one. To us who watched this case very carefully the conviction is as strong as could be made by a solitary example.

REPORT OF THE LYING-IN SERVICE AT CHARITY HOSPITAL, BLACKWELL'S ISLAND, FOR THE YEAR 1874.

By ROBERT WATTS, M.D.,
ONE OF THE VISITING PHYSICIANS.

Of the numerous changes made in the hospitals under their care by the late Board of Commissioners of Public Charities and Correction, one of the most important was the closing of the lying-in service at Bellevue and the transfer of all lying-in women to Charity Hospital.

The closing of the service at Bellevue had become a necessity, for the mortality among lying-in women, which for several years had been large, became in the early months of 1874 so alarming as to compel the Commissioners to find another place for the treatment of this class of cases, and at the suggestion of the Medical Board of Charity Hospital they decided to transfer all the waiting women then in Bellevue to Charity, and to send all pregnant women applying for relief thereafter to the same hospital.

This change was regarded unfavorably by many members of the profession, and by the public, who thought it was simply a change of location which did not insure any more safety for the patients than was afforded at Bellevue; and it was consequently made with some apprehension.

That these fears were groundless the results, we think, have demonstrated, and as these results have been even more favorable than we dared to expect, they are now published in the hope that they may prove of interest.

The wards in Charity, four in number, which were assigned for the lying-in service are situated on the top floor of the west wing of the building and have windows opening to the north and south. Occupying the whole of the top floor of that wing, they are entirely separated from the rest of the hospital.

The records of the hospital show a total of 431 lying-in patients for the year ending January 1st, 1875, of whom 23 were confined outside and afterwards brought to the hospital. The mortality for the year was 11, or one death in 39 $\frac{1}{11}$ cases.

TABLE II.—TOTAL NUMBER OF DEATHS FROM PUERPERAL DISEASES IN CHARITY HOSPITAL DURING 1874.

No.	Date.	Name.	Age.	Social condition.	Primipare	Multipare	Character of labor.	Cause of Death.	Remarks.

On the 11th of June, 1874, the lying-in wards at Bellevue were closed, and twenty-three waiting-women were transferred to Charity. It was not deemed safe to put these with the waiting-women in the main building, and they were consequently put in a pavilion to the south of the hospital proper.

Of these twenty-three women fourteen were single, nine married. They had come directly from the infected wards of Bellevue, and, although the temperature of all those who were confined in there the first two weeks after their removal averaged considerably higher than in the patients who had not been in Bellevue, no case of puerperal fever occurred among them.

During the year there occurred fourteen cases of puerperal diseases, of which eleven died and three recovered.

By reference to the tables in an article published by Dr. Wm. T. Lusk in the August number of the *New York Medical Journal*, page 158, it will be seen that there occurred in Bellevue during the year 1873, out of 449 confinements, thirty-one cases of puerperal diseases which could fairly be attributed to hospital influences.

A proportion of 1 to 14 $\frac{1}{2}$, with a mortality of one to thirty. If the statistics of the lying-in service at Bellevue for 1874 up to the time of its close were published, they would show an enormously increased ratio both of puerperal diseases and of deaths.

An analysis of Tables II. and III. preceding shows that out of the fourteen cases of puerperal diseases occurring in Charity during 1874 only seven can be attributed to any septic influences existing in the hospital. A proportion of 1 to 61 $\frac{1}{2}$, while of deaths attributed to similar causes there were only six, a proportion of 1 to 71 $\frac{1}{2}$.

was attributable to poisonous influences existing in the hospital, and not, as Dr. Lusk intimates, to the social condition of the patients.

In conclusion, we desire to correct an error in Dr. Lusk's paper, wherein he speaks, page 159, of the "closure of Charity Hospital to this class of cases in 1869, on account of its having been visited by a severe epidemic of puerperal fever," and again on page 164, "in 1871 it" (meaning Charity) "had to be closed on account of puerperal fever." Since the establishment of a lying-in service in Charity in 1869 the service has never been closed, nor has the hospital

TABLE III.—TOTAL NUMBER OF PUERPERAL DISEASES IN CHARITY HOSPITAL, IN 1874, FROM WHICH PATIENTS RECOVERED.

No.	Date.	Name.	Age.	Social condition.	Primiparae.	Multiparae.	Character of labor.	Disease.	Remarks.
1	Mar. 14	L. K.	30	M.		M.	Normal.	Convulsions.	
2	May 9	N. D.	21	S.	P.		Normal.	Puerp. Fever.	
3	Sept. 4	J. R.	17	M.	P.		Normal.	Remit. Fever.	

The death rate from puerperal diseases among primiparous women in Bellevue and Charity shows a marked contrast between the two hospitals, for while in Bellevue it "rose to five and a half per cent.," in Charity it was only one per cent.

From these figures it seems evident that the large amount of puerperal diseases occurring in Belle-

ever been visited by a "severe epidemic of puerperal fever." The immediate transfer of all the other lying-in women from a ward in which a case of puerperal fever has developed to a ward in another part of the building has enabled us, thus far, to prevent the spread of the disease and avoid anything approaching in severity to the dignity of an epidemic.

Progress of Medical Science.

THE ADVANTAGES AND DISADVANTAGES OF ESMARCH'S BLOODLESS METHOD.—A paper on this new method was recently read before the County Medical Society, by Dr. Henry B. Sands. The object of the paper was to give a summary of the operations in which it was employed, in the city of New York and its vicinity, during the first year of its trial here, and in connection with the results obtained to devise an estimate of the value of the method. The record of instances in which it was employed comprised a list of 143 cases, tabulated so as to indicate the nature of the operation, and, in the fatal cases, the cause of death. Upon the whole, the experience appears to have been very favorable to the new method. In the only instances where evil results seemed to have been due to the application of the elastic bandage, they were more fairly attributable to the mode of its application than to the method itself. It was stated that certain advantages of the method were unquestionable. As to its bloodless character, Dr. Sands regards it as almost perfect, and says that there is only a loss of a few drops of blood during the operation, and the loss of blood from oozing which occurs after the constricting band has been removed is far less than the gain by this new method over the older method. After the completion of the operation, the patient has often a relatively greater supply of blood in his body than before the operation was commenced. An interesting point alluded to in this connection is the apparent impunity with which the vascular system suffers this sudden increase or tension. It is, however, suggested, that in case of thoracic or abdominal disease the sudden distension of the vessels with blood may possibly be attended with danger.

Besides the immediate advantage to the patient of

the bloodless operation, the method becomes of vast service to the surgeon under circumstances where deep dissections are necessary, as for the removal of tumors or foreign bodies, or in searching for a deeply-seated wounded vessel. Under these circumstances a clear and unobstructed view of the tissues that come under the knife is very desirable. While the parts are stained and obscured by blood, important structures may easily be wounded or injured, which, with the aid of Esmarch's apparatus, might be safely avoided. This, however, does not wholly apply to the blood-vessels, their emptiness rendering them somewhat difficult to be recognized. As a precaution, therefore, it is advised that the operator "make good use of his anatomical knowledge, and study the appearance of the tissues before he divides them."

There is another use to which Esmarch's apparatus might be put, as observed by the writer, viz.: in those cases where compound fractures are attended with free hemorrhage, and it is suggested that were ambulance surgeons and those in charge of the police stations supplied with the apparatus, it would frequently be the means of saving life.

The possible disadvantages of the bloodless method are considered under the heads of sloughing, secondary hemorrhage and paralysis. These mishaps all occurred in the cases collected, and in several instances were clearly due to the employment of Esmarch's method. Still in each of these instances there was reason to suppose that the method had not been properly applied. With regard to the applicability of the bandage, it was observed that it is desirable to abstain from its employment in certain cases, and above all to learn the minimum degree of pressure that will accomplish the desired result. The bandage should be soft and highly elastic, and the constriction of the limb should be made either by a piece of the same material, or, where this would be too wide, by a piece of soft rubber tubing. The solid cord shank, he thinks, be abandoned, as likely to do mischief. The

constriction should also not be applied for a longer time than absolutely necessary, the danger probably increasing with the length of time the pressure is continued.

THE REMEDIAL USE OF WATER.—The use of cold water as a therapeutic agent was made the subject of much study and research in the latter part of the last century by James Currie. His investigations were embraced in a book of two volumes, which at the time of its publication created no little interest, but has since fallen into comparative oblivion. Recently, however, the views which were then expressed have been revived, and Liebermeister, in his article on "Typhoid Fever," in *The Cyclopaedia of the Practice of Medicine*, refers to Currie as the first who used the cold water treatment systematically and according to certain clear indications in febrile affection. In the last number of *The American Practitioner*, Dr. Austin Flint gives an analysis of Currie's work, making it the basis of a very interesting article on "The Remedial Use of Water."

As is well known, the cold water treatment has been more in vogue in Germany than elsewhere, but its employment has been gradually extending, and Dr. Flint thinks that he discovers indications that it will soon become much more general. "One tendency of the popular mind," he observes, "towards the potency of water as a remedy for the past twenty years or longer, dating from the rude empiricism of Priessnitz, has in some measure preface the way for its regular and scientific employment. It has been obvious that the so-called "water cures," and "hydropathic institutions," in which routine methods of treatment are employed, conducted often by ignorant men without discrimination, nevertheless do good, together with much harm; in other words, beneficial results are obtained in a certain proportion of cases. Hence some establishments in which water is recognized as a prominent remedial agent are now under regular medical direction, and hydropathy may be said to have become in a certain sense legitimated."

At the present day the advocates of cold water treatment employ it for its antipyretic effect only. It is solely for the purpose of reducing the excessive heat of the body, which is now regarded, not as an effect merely of the internal disorder, as Currie thought, but as of itself capable of doing great damage to the system, and as a cause *per se* of serious structural derangements and even of death. The abstraction of heat from the body therefore is a great desideratum in fever, and the application of cold water to the heated surface has this object simply in view. Currie, also, on the other hand, believed in a certain remedial effect that was due to the sudden impression upon the nervous system, and therefore he preferred affusion as the mode of application.

A large portion of Dr. Flint's article is occupied by an abstract of Currie's experience as related in his book. The time devoted to this work appears by no means misspent. Little that the book contains would seem antiquated in the most advanced literature of modern therapeutics. Indeed, in one respect it would appear that Currie's art was in advance of modern methods of treatment. We are apt to be content if we succeed in a measure in abating the intensity or danger of a fever, but Currie aimed—and apparently with no little success—to cut the disease short. The contrast in this respect is striking, and suggests the inquiry whether it may not be true that the use of water by affusion has a potency as an abortive measure of treatment which does not belong to the bath. Finally, the use of the cold bath after the practice of

Liebermeister and others of the German school at this day is as much at variance with—or, if the expression be admissible, in advance of—the usual treatment of the essential fevers and acute inflammations as was the employment of cold affusions in Currie's time.

Dr. Flint also refers to the use of the wet-pack, and in this connection mentions a method of its employment which he has found advantageous. The patient is wrapped in the sheet saturated with cold water in the usual manner, and then as often as the covering becomes warmed through the heat of the body the cold water is again sprinkled over it from an ordinary watering pot. This is continued until the thermometer registers the desired temperature. The experience with this method was mainly obtained from its use in a large number of cases of sun-stroke at Bellevue Hospital during the summer of 1872.

In conclusion, some interesting observations are made with regard to the remedial use of water internally. The suggestion is thrown out that possibly no little share of the benefit derived from the mineral waters is due to the ingestion of large quantities of water. It would have been interesting had Dr. Flint enlarged somewhat more upon this point. Finally, allusion is made to the potency of water, used internally to promote the secretion of urine in renal disease, and he relates a case of tubal nephritis with convulsions, which was apparently quite cured by that means.

A MODE OF REDUCING STRANGULATED HERNIA.—In a recent number of *La France Medicale* it is reported that the following method was adopted by Perrin as a novel procedure in the case of an inguino-scrotal hernia, which had become strangulated, and in which serious symptoms had already shown themselves. Taxis had been thoroughly tried under an anæsthetic, but without success. An attendant was therefore directed to take hold of the patient's legs, and placing them on his shoulders to raise him up until he rested only upon the shoulders and head. The body being thus very strongly flexed forwards, the integuments of the abdomen became so relaxed that Perrin was able by manipulation to reduce the hernia to one-half its former volume, by the return of the fluid which the sac had contained, into the peritoneal cavity. The patient was then placed in the horizontal position, and the gut was completely restored. There is hardly any novelty, however, in this operation, for American surgeons, have practised it in repeated instances.

PENGHAWAR DJAMBI AS A STYPTIC.—This plant is a native of China and the East Indies. It belongs to the order of ferns, and is said to have styptic qualities. The parts used for this purpose are the hairy raments found on the backs of the stems and fronds. Dr. Hainze, in referring to its use, says that he has employed it exclusively to arrest the excessive bleeding from leech-bites or after phlebotomy, but he also relates a case of hemorrhage from the temporal artery, and another from the anterior tibial, where a pledget of the penghawar promptly stopped the flow, though for twenty-four hours previously various other means had been ineffectual. He attributes its styptic character to the fact that the blood in passing through the hairy fibres is entangled by them. Vogl, on the other hand, believes that it owes its character to the fact that the alkaline and watery elements of the blood are taken up by the fibres, which then become swollen. Schroff believes that the paleæ of *eliotium glaucum*, another and very similar fern, known in the Sandwich Islands as *polu*, and exported in large quantities as material for stuffing cushions, would probably answer the same purpose and be cheaper.—*Aertzl. Corr-blatt., Rundschau*, Nov., 1874.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, January 30, 1875.

THE VALUE OF AMERICAN DIPLOMAS.

IN a recent number of the London *Lancet* is an editorial upon the subject of medical education in this country. The whole tenor of the article is so calculated to give a false impression of our systems of instruction, and the real value of our recognized diplomas, that we feel called upon, in the interests of American medicine, to offer a word or two of explanation. We are surprised that a journal of the standing of the one in question should allow itself to be so thoroughly misled in questions of fact which should be palpable to every one at all conversant with our systems. A few bogus diplomas, claiming to come from America, have been discovered in Great Britain, and this circumstance furnishes the text for a high-toned moral sermon on the value of our diplomas generally. While admitting that there must be much admirable teaching in the United States, the inference is, however, very clear that, in the opinion of our cotemporary, the majority of American diplomas are bought and sold like any other marketable commodity, and that the greater number of these guarantees of medical education "bear no comparison even with the lowest of our British qualifications." We do not claim that we are perfect in our system of medical education, we acknowledge that there is great room for improvement, that many of our colleges are not as strict as they might be, but we are not prepared to admit that we encourage fraud, abet swindling, or countenance forgery.

To presume to hold the profession of America accountable for the action of a few scoundrels, is simply ridiculous, and were it not for the animus shown would be unworthy of notice. *The Lancet* knows full well that we have many admirable medical schools, that the profession here is keenly alive to all the requirements which should constitute a first class medical education, and that the schools themselves not only vie with each other in raising the standard of medical teaching, but are jealous of the distinction of

leading the van. These are palpable facts, an ignorance of which is a reflection upon the ordinary common sense of any writer who attempts to sit in judgment upon our actions, or presumes to impugn our motives. As a profession we are very jealous of the value of our diplomas, and no body of men in this country were more active in exposing the shameless, abominable and outrageous frauds of the diploma traffic by the bogus college in Philadelphia, and none were more instrumental in depriving that institution of its charter.

With our system of government we cannot prevent swindlers of any class from imposing upon the public, and if some of the tricks of those individuals take with some of our British cousins, we are always ready to pity their stupidity and warn them in future. This is an act of ordinary charity to people who will persist in becoming the easy prey of a few sharpers. The knowledge displayed of some of our American schools is quite amusing, and is in keeping with the general information concerning medical matters in this country. The Medical department of Yale College is referred to as "the Yale University, Massachusetts," and the College of Physicians and Surgeons of this city as "the New York Columbia University" (!) There may be an institution of that sort in this city which can grant diplomas recognized by our British friend, but we are ignorant of it.

It is very true that our colleges are quite numerous; that they are self-constituted corporations; that, technically speaking, we have no legal enactments, which hold these institutions accountable for the qualifications of their graduates. Experience has shown that it is useless to ask any legislature to fix the standard of such qualifications. The profession, however, has made a standard of its own, and has refused to recognize colleges which do not give a thorough course of instruction to its students, and which do not demand, at the end of a period of three years' study, a thorough examination. The number of these medical colleges so recognized by the American Medical Association can be seen by a reference to our advertising columns. A diploma from any of these institutions is accepted by the profession as the guarantee of a good medical education. To obtain a diploma from recognized schools of medicine by fraud is a simple impossibility. Although we have said this again and again, we will repeat it for the benefit of such as persist in being ignorant of the fact. We cannot prevent the people from employing quacks. The responsibility for so doing rests with them, not with us. The inability to prevent quackery outside of our ranks by no means implies that we encourage it.

Reference is made in the article in question to the operation of the new law regulating the practice of medicine and surgery in this State. This law is by no means a perfect one, and the majority of the profession are not in favor of it. The intention of the framers was to prevent quackery in some of its more glaring forms. In our own county it has accomplished some

good. The board of censors of every county society is empowered to examine every one throughout the State practising without a diploma. In this county alone seventy have been thus examined, and only six passed a satisfactory examination. The successful candidates are not made licentiates of their different county societies, but only receive a certificate of satisfactory examination from the censors. It is not our purpose to discuss, at this time, the general merits or demerits of the law, but merely to state a question of fact bearing upon the general subject of medical qualification in America.

CHANGE OF TIME AND PLACE FOR THE MEETING OF THE STATE SOCIETY.

WE have repeatedly called the attention of those of our readers who are interested in attending the State Society, to the necessity of changing the time of meeting. Two years or more ago the feasibility of such a plan was left to a committee, which reported in its favor, giving at the same time the reason upon which its opinion was founded. The matter was made the special order of business for a certain evening, and while every one appeared to be in favor of a change of time, no one seemed ready to come to any definite conclusion, until one gentleman suggested that such a change might interfere with the legislative business of the Society, or rather with that business of the Society which necessitated the presentation of proposed laws, resolutions, etc., to the Legislature while in session.

If such an objection ever had any weight it is certainly removed at present. The sentiment of the Society is now so entirely adverse to any attempt to secure legislative interference in behalf of itself or of the profession, that it does not even ask the Legislature to publish its transactions. We have declared our entire independence of any such aid, and the advantage of having our meeting at the present time amounts to nothing. This has heretofore been the only argument in favor of holding the annual meeting at the most inclement season of the year, at the time when the most of our medical teachers are actively engaged with their classes, when most of our practitioners are absorbed in the duties of the sickliest season of the year, and last, but not least, when on account of the session of the Legislature, the annual meeting of the Masonic and other associations, the hotels of Albany are in their most crowded condition.

We do not undertake to name the precise time of the year when the meeting could be held with the greatest advantage to the members, but we do venture to say that a more unfavorable season could not have been selected. Prof. White, in his inaugural address delivered in 1870, gave some very good reasons for changing the time to the early fall, and we take occasion to quote them in this connection for the consideration of the members at the next session.

“The fall season presents more advantages than any

other, as a time for the annual meeting. There is, as a rule, a comparatively healthy period in the latter part of September, when practitioners will find it more convenient to be absent from their patients, than in the busy season of winter. Then travel is more agreeable and easy, the hotels in Albany are not overcrowded, and there would be a better choice for rooms of assemblage.”

The committee appointed in 1873 to report on changing the time of meeting, recommended that season, but for reasons already stated the report was, in the hurry of more pressing business, consigned to the table without being fairly discussed, and with but one objection urged against its adoption. We are glad to learn from the President of the Society, Dr. Fisher, of Sing Sing, that he intends, in his inaugural, to advocate the change, and this action on his part will be the best possible excuse for the Society to take up the matter afresh in the regular way of a report of the committee on the President's address. We believe every member in the State is ready for the question, and it is hoped that the matter will be settled at the coming session. If there is once a decision by the Society there will be no possible difficulty in obtaining legislative sanction, for in reality it is a matter of supreme indifference to them when we meet, how we meet, or where we meet.

Having said thus much in regard to changing the time of meeting, we have a remark or two to offer in favor of a change of place for the meeting. There being no further necessity for pinning ourselves to the apron-string of the Legislature, there is in reality no necessity for meeting in Albany. It is true that city has furnished us with a goodly number of presidents, vice-presidents, permanent members, receptions, supporters, secretaries, executive committees, and publication committees, until we begin to think that nothing can be done for the Society unless it is accomplished there. In fact, some evil-disposed members who do not live in Albany have said some cruel things of an Albany ring, but these malcontents forget that they have forced the Albanians to take on the management of the Society, and, far from finding fault, should give them the credit of managing it exceedingly well. But the question comes up at this time, whether these gentlemen have not already done enough to merit the everlasting gratitude of the Society, whether it would not be magnanimous, to say the least, to make a change. We are, in view of the necessities of the situation, decidedly of such an opinion. We are not in favor of any particular city for a permanent meeting place, but believe that New York should be the headquarters. There is hardly a member of the Society living outside of Albany who would not wish to meet at least once every other year in this city, who would not take more pleasure in visiting our hospitals, libraries and colleges, than in a supper at the Delavan or a reception by the Governor. Is it any longer necessary to have a committee of publication from Albany? Can the

transactions be published in no other place so promptly or so well? If so, we are willing to admit that there is no necessity for any change. The committee whose duty it will be to nominate officers for the ensuing year should give these matters their consideration. We do not see any objection to meeting every other year in the different large cities of the State. This would certainly be agreeable to the majority of the members, especially if the time of meeting is changed to the fall. In conclusion, we believe we are warranted in saying again, that the "Society is ready for the question."

SCHOOL HYGIENE.

SUPERINTENDENT KIDDLE in his last annual report, thus speaks of the sanitary condition of our public schools:—

"Too little regard has been had to the space which should be allotted to each pupil in the construction of the school buildings, with a view to both comfort and ventilation. In many class-rooms of the primary departments and schools, only about thirty cubic feet of air to each pupil is possible to be given, even with all the windows and doors open. In some recitation-rooms only forty or fifty cubic feet is afforded. The sole consideration in furnishing the school-rooms seems to have been in these cases to crowd as many seats together as possible. Serious maladies are frequently contracted by the pupils in these schools, because of the necessity of opening the windows even in the coolest weather. There should be, in all grades of pupils, a uniformity of treatment, mental, physical, and moral; but the fact exists that the pupils of grammar schools are furnished, in nearly all the school buildings from one hundred to one hundred and fifty cubic feet of air per pupil."

This looks very much like waking up to the necessities of the occasion. It would, however, be strange indeed if, after so much exposure of the insanitary condition of our schools the Superintendent did not force himself to say something upon the subject, and make some suggestion. Here is a report of progress. The next thing is to re-establish sanitary inspection. But under the existing circumstances this is a very hard thing for the Board to do. Probably the only excuse now is, that such a course would be the violation of one of its principles.

ONE DISADVANTAGE IN TRANSFERRING LABOR CASES TO CHARITY HOSPITAL.

THE necessity for a Maternity Hospital, located in the city, is now more apparent than ever. The interference with navigation, caused by the ice which collects in the East River, threatens at times to cut off all communication with Charity Hospital for hours together. When the wards of Bellevue Hospital were open to obstetrical cases, the so-called "street cases," or those coming into the hospital after labor had already commenced, formed a considerable proportion of the whole number. From the hardships which they

had endured, or the unavoidable delays in their admission, these patients were, in many instances, the ones whose death gave so unfavorable a coloring to the hospital statistics, or by their unhealthy conditions contributed in no insignificant degree to the unhealthfulness of its wards. The need for medical attendance at the earliest possible moment caused the Medical Board of Charity Hospital, some time since, to detail one of the House Staff to receive obstetrical cases at the dock-house, at the foot of Twenty-sixth street, but even this has not prevented patients dying *in transitu*, or while awaiting at the dock the tardy and infrequent means for communicating with the Island.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1875.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

MINUTES of last meeting were read and approved. The President's address upon retiring from office was next in order. It came like words fitly spoken, and was listened to with marked attention.

The circumstances and events which have characterized the transactions of the Academy during the last two years were briefly recounted. Reference was especially made to the arrangements that have been completed for placing papers read before the Academy in the hands of the printer as soon as the Council has passed upon them. In this way the papers can be given to the profession early, and the medical journals in which they may subsequently be published can give due credit to them as coming from the transactions of the Academy.

Reference was made, in congratulatory terms, to the fact that a building had been secured for the Academy and the profession of the city.

The propriety of holding weekly meetings of the Academy was suggested, with the view of giving more time to the discussion of papers that might be read.

At the close of the address Dr. Flint retired from the office of President of the Academy, by presenting a copy of the by-laws to the newly-elected President,

Dr. Samuel S. Purple.

DR. PURPLE then delivered his inaugural address. The Doctor first made quite extended reference to the objects contemplated in the organization of the Academy, and closed with the following special recommendations:

First, That a sinking fund should be created at once for the purpose of meeting the debt just incurred by the Academy.

Second, That an effort be made to establish a medical library. This was once made in that direction, as far back as 1847, but one probable reason of its failure was the lack of a proper room in which it could be placed. That obstacle was now overcome by the purchase of a house for the Academy. He suggested that the formation of a committee be referred to the Council, and believed that another effort in this direction would be crowned with success. At the close of the address.

DR. VANKLEEK offered the following resolutions:

Resolved, That the thanks of the Academy of Medi-

cine are eminently due and are hereby tendered to our retiring President, for the able, dignified, impartial and satisfactory manner in which he has discharged the duties of his office during the past two years. Unanimously adopted.

Resolved, that the suggestions and recommendations embraced in the addresses of the evening delivered by the late and present President of the Academy be the same, and hereby referred to the Council. Adopted.

DR. AUSTIN FLINT offered the following:

Whereas, The Council of the Academy did at their last meeting approve of the transfer of the building fund now held in custody by the Trustees, to the Committee of Ways and Means: be it

Resolved, That the Trustees be hereby authorized and directed to transfer the whole amount of the building fund to the Committee of Ways and Means, to be used for the specific purpose of purchasing a building for the Academy upon West Thirty-first Street, in the city of New York. Adopted.

DR. ANDERSON hoped those who had subscribed and had not paid their dues, would be kind enough to attend to the matter early, and pay to the Treasurer of the Committee of Ways and Means the amount of their subscription, as a payment must be made upon the first of February next.

ICHTHYOSIS OF THE TONGUE.

DR. WIER then read a paper upon "Ichthyosis of the Tongue." The disease possesses some interest because of its surgical relation to epithelioma of the tongue.

The doctor gave a brief historical account of the disease reaching as far back as 1837, embracing the history of fifty-eight cases. To these were added ten cases, part of which had fallen under his own observation, and part had been furnished him by his professional friends. One was noted as being the only one upon record in which this disease was seen upon the vulva.

Some of the cases were associated with the habit of smoking, some were not; some were associated with syphilis, and some were not; and some of the cases occurred in persons with a psoriatic diathesis.

Between ichthyosis simplex and ichthyosis syphilitica, he was not able to draw any reliable diagnostic lines.

With regard to treatment: caustics are used and are not used, they were perhaps of doubtful efficacy; alkalies in the form of spray seemed to be sometimes serviceable; and some urged excision of the tongue.

DR. WEBER remarked that he regarded it as important to distinguish between the simple cases and the syphilitic variety, because observations at the clinique of Thiersch had led him to the conclusion that it was only the simple cases that eventually degenerated into epithelioma.

DR. R. W. TAYLOR joined in the discussion.

DR. ADAMS introduced the following resolution:

Resolved, That the delegates from the Academy of Medicine to the State Medical Society be instructed to urge at the next meeting of that society, a change of time for holding its meetings, from February to June. Adopted.

The Academy then adjourned.

THE GRADUATING EXERCISES IN THE MEDICAL SCHOOLS will be held as follows: Medical Department of the University of the City of New York, at Steinway Hall on the evening of Tuesday, February 16th; Bellevue Hospital Medical College, at the Academy of Music on the afternoon of Thursday, February 25th; College of Physicians and Surgeons, at Steinway Hall, Monday evening, March 1st.

Correspondence.

THE VALUE OF SPECTRAL ANALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Various propositions, contained in my lecture before the Medico-Legal Society, "On the Importance of Spectroscopic Analysis in Forensic Cases," are controverted by Dr. Henry G. Piffard in THE RECORD, Nov. 11, 1874, who contends "that I have incorrectly stated questions of fact in Spectral Science, and that I claimed more for the spectroscope than the facts warrant." In speaking of the sunlines, I stated that "Kirchhof has left us a map of these, a masterpiece of correctness and skill, containing many hundreds of sunlines, and our distinguished Rutherford has photographed them from the sun." The critic reminds me that only a small number of Kirchhof's lines "are delineated on Rutherford's map, and that many others, especially those more refrangible than the H line, were never seen by Kirchhof."

I am not aware that I have anywhere stated that Rutherford photographed ALL sunlines from the sun itself. I desired to convey the idea that sunlines were thus photographed, nothing further. The two sections of mappings to which I had reference were those published by Professor Roscoe, in his work, "Spectrum Analysis," page 206, second edition; they contain each about 130 sunlines, laying between E and G, extending from the 194th to the 220th degree of Kirchhof's scale. This being my reference on the two sections of mappings, it will be seen I must have been in full possession of all information so ostentatiously offered by Dr. Piffard.

In my lecture I stated that Professor Draper has given us a map containing a great number of sunlines, invisible under ordinary circumstances; these lines are made evidently at the red and violet part of the spectrum. The human retina is not sensitive to light waves beyond the red and violet part of the spectrum.

From this he forces the fallacious inference that I thereby meant the whole range of sunlines in red, orange, yellow, green and blue!

In my aforesaid lecture I stated that sound, heat and light are produced by vibrations; that those least in velocity and wave lengths produce sound; those next in velocity, heat; and those highest in velocity, light.

I am reminded that sound-waves are produced in the atmospheric air, and that they travel in the same direction as the waves progress. All I desired to convey was the close analogy existing between sound, heat, light and motion. That the denser medium of the atmospheric air furnishes the conditions necessary for the production of sound, I freely admit as a universally acknowledged fact.

Whether the ether is effected by condensations and rarefactions of the atmospheric air in the production of sound is, I claim, an open question. Professor Lovering, in his address before the American Association, Hartford, Aug. 14, 1874, asks: "How is the ether affected by the gross matter which it invests and permeates? Does it move when they move? If not, does the relative motion between the ether and the other matter change the length of undulation on the time of oscillation? Evidently there is an obscurity in the minds of many physicists, and an uncertainty in all, when they reason upon the mechanical constitution of the ether and upon the fundamental law of light." Whilst I have no desire to place myself in antagonism to the prevailing theory on the existence of a cosmic ether, I

am not unmindful that the existence of such an ether is denied altogether, and that there are physicists who insist that what is called ether is nothing more than atmospheric air in its highest state of rarefaction. (Schellen's note, p. 56.) Schellen says, *Spectral Analysis*, p. 65: "To the physicist the words color and sound are only modes of expression, for phenomena similar to, and thoroughly related to, each other." The difference between the oscillations of the air and the ether consists only therein that, at the immensely great firmness and elasticity of the ether, not only does the propagation of the ether oscillations take place much quicker than in the coarser and more graver particles of the air, but also *because the number of oscillations per second is so exceedingly great that they must be counted by the billions.*

Strange indeed that Dr. P. lays more stress upon the longitudinal direction of the sound waves than upon their velocity and wave lengths, which he seems to ignore altogether!

I am further reminded "that the vibrations of heat and light take place in the luminiferous ether, and that the light waves travel at right angles."

This luminiferous ether seems to be to Dr. P. a scientific fact of which he knows and understands everything, whilst to me and to many others it is simply an ingenious hypothesis, "with wonderful facility of adaptation to each new exigency in optics."

Stall says of this luminiferous ether: "It is nothing but a cloth horse, for all the insoluble difficulties presented by the phenomena of sensible material existence."

How heat and light are produced in this luminiferous ether, simply by travelling at right angles without acknowledging the agency of velocity of wave motion, differing for sound, heat and light, and which Dr. P. seems to ignore, I am not able to understand.

I have before me both the works of Dr. A. Nagel and Dr. H. Schellen; neither of them say anything about the longitudinal course of sound waves, nor of the transverse direction of light waves; yet would it not be preposterous to assume, as Dr. Piffard has done in my case, that on that account these physicists were ignorant of these physical laws?

The statement that five metals were discovered by the aid of the spectroscope was made on the authority of Professor Roscoe, in the first edition of his book on "Spectrum Analysis."

What I said in my lecture upon the stability of hæmato-crystalline, and of its wonderful fitness to sustain the functions of life, I maintain with unflinching conviction. It must be evident to the unbiased mind, that reference is here made to the crystallizable material of the blood, and not to the artificially prepared crystals, to which Dr. P. evidently refers. Let us look at the facts. Experiments, which I have repeatedly made, with old dried blood from man, have revealed to me the wonderful integrity of this substance, "the crystallizable material of the blood." These experiments, made especially with the blood of man, were published in the "Archives of Scientific and Practical Medicine," edited by Dr. Brown-Séquard, 1873, No. 5. They have passed the scrutiny of eminent physicists at home and abroad, and they stand uncontradicted to-day. Has Dr. P. repeated these experiments and attained different results? This course would be the only legitimate one to pronounce upon this subject. His unsupported opinion amounts to absolutely nothing. When I take a specimen of dried human blood, nearly six years old, and obtain from it the well-known oxyhæmato-crystalline bands, and when I find that such blood solution can be oxydized

or deoxydized at pleasure, just like fresh blood, it is to me ample proof that the hæmato-crystalline *has not* been destroyed; it is striking evidence that ordinary atmospheric changes *do not*, as alleged by Dr. P., affect its integrity. As no substance known, is absolutely indestructible, I do not claim it for the hæmato-cryst. In my lecture under consideration I have pointed out the changes of this substance under the influence of chemical agents, under the head of "optic relations of blood," p. 532, and have furnished a diagram, marking their corresponding spectral appearances. Dr. Thudicum, in his report to the Privy Council, 1868, says that hæmato-crystalline is the last ingredient of the blood which undergoes putrefaction; it preserves its color and its spectrum for years in horribly offensive mixtures, to which air has only a moderate access, and adds, "that the stability of hæmato-cryst. is the main factor in the stability of life." The same unqualified view is taken by Dr. Valentin and Hugo Schiff, who experimented with old putrid solutions of blood, four years old (see "Der Gebrauch des Spectrosopes," pp. 95 and 97), and where he stated that such blood, four years old, might be used in medico-legal cases as well as fresh blood. The same view precisely is expressed by René Benoit, in his "Etudes Spectroscopique sur la Sang," p. 62. In point also is the case cited by Dr. Galletin in his lecture before the Academy, October 5th, 1871.

Were it not for want of space, many, many more authorities could be quoted to sustain my position to the fullest extent, where not one is known to sustain the "critic."

So also must I maintain what I "said in my lecture," that when the outer form of the blood corpuscle is destroyed by chemical or mechanical means, we may demonstrate blood by producing the crystals!

Here Dr. P. exclaims: "The fact is that crystals of hæmato-cryst. can only be obtained from fresh and not from dried or chemically altered blood!" Alas for Dr. P. ! he recurs with incorrigible fallacy to the artificial hæmato-crystalline. Pryer, the best authority on this subject, says in his work, "Die Blutcrystalle," p. 5: "Blood crystals are not only hæmato-cryst., but Teichman's Hæmin, Hæmatin, Hæmatoidin and Hæmatoïm." When and where did I say that from chemically altered blood we may obtain hæmato-crystalline? Nowhere. Why, let me ask, may not hæmato-crystalline be obtained from dried blood? So long as a solution made from dried blood responds to the spectrum test, showing the characteristic bands described by Hoppe, Seyler and Stokes, so long as it can be oxydized and deoxydized at pleasure, so long must hæmato-crystalline be present, and the blood solution must yield it. Dried old blood may not be the best source from whence to obtain it artificially and in quantity. Can Dr. P. point out any authority, or has he made the necessary experiments, to justify him in saying that it cannot thus be obtained?

Blood altered by carbonic oxyd, nitrous oxyd and prussic acid yields crystals of peculiarly firm stability. It is the possibility to produce this long list of crystals, and to recognize them by their peculiar modification of the spectrum, that furnishes us positive proof of the presence of blood, long after the blood corpuscle itself is broken up and its outer form destroyed!

It is thus that Newrock demonstrated a very small quantity of blood from a putrid solution of urine and milk, by producing the hæmatin-crystals, and Virchow has succeeded in a forensic case to prove the presence of blood by producing the crystals of Hæmine (Cellular Pathology, p. 178).

The proposition is fully corroborated by Dr. Thud-

icum, p. 170, Tenth Report, and Dr. Bird Herapath relates a case, the Government against Robert Coe, Swansea Assizes, where blood was demonstrated in quantity not exceeding ten $\frac{1}{1000}$ parts of a grain, after having been exposed to the elements for weeks.

I might go on to pile authority upon authority; enough, I think, has already been presented to prove fully my position and to disprove the assertions of Dr. Piffard! And now about the ash of human remains! I think it possible that the remains of any warm-blooded animal may give an identical spectrum. I possess no data on this point; possibly there may be a modification. But the fact that the remains of man, say if you will the animal remains, give a peculiar spectrum is of the greatest importance. In given cases it may furnish the missing link in the chain of evidence, which may tend to fasten the criminal act upon the true criminal!

With regard to the practical procedure to analyze a metal or a mineral poison, I have pointed out how this is accomplished by means of Mitcherlich's and Becquerel's Apparatus, on page 534.

Speaking of the Wharton trial, Dr. P. asks, "What is the spectrum of gelsemium? In answer I say: No spectrum of this drug is known to me, and yet I reiterate that the spectrum test could have given as the information whether the substance found was arsenicum, antimony or gelsemium. The spectra of the two metals arsenicum and antimonium are well-known, and were directly available. In case the spectrum of one or both metals could have been produced it would have been a strong presumption of Mrs. Wharton's guilt. In case the substance gave no spectrum of these two metals, it admitted the possibility of its being gelsemium by exclusion, and would have strongly pointed out the innocence of the accused, she having no responsibility for the administration of this drug.

Having answered all questions of the critic, I may be allowed to make a remark or two in defence of my positions:

My labors having passed the scrutiny of able physicians abroad and at home, it was natural for me to expect on the part of one who chose to have an opinion contrary to mine that such an opinion should be expressed in a candid and manly way, and that the very disinterestedness of my researches should have protected me from rude personal assault. I regret that Dr. P. has seen fit to act otherwise. Comment on such a course, however, is unnecessary. I am conscious that, as the pioneer of spectral analysis, applicable to medicine, in this country, I have recorded with the utmost fidelity the progress made in this branch of our medical science; I have added some original researches which are quoted as authority, and I am contented to rest upon the verdict thus far rendered by *my peers* at home and abroad.

S. WATERMAN, M.D.

HOSPITAL FOR SMALL-POX.—Some time since the Commissioners of Public Charities constructed a pavilion upon a pier opposite Bellevue Hospital, for the reception of small-pox and fever cases until they could be transported to the Island. It is said that the Health Board, who now have the charge of the small-pox hospital, intend to use this pavilion for the accommodation of the better class of paying-patients, who will thereby avoid the discomforts and risks attending the transit to and residence in the small-pox hospital proper.

RESECTION AS A REMEDY FOR ABDUCTION OF THE GREAT TOE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Having read in THE MEDICAL RECORD of January 15th, 1875, an article by Dr. A. C. Girard, U.S.A., on "*Resection as a Remedy for Abduction of the Great Toe.*" I desire to communicate another case which lately occurred in my practice.

A. C., fifty years old, born in Ireland, laborer, was received into the St. Francis Hospital, October 24th, 1874, suffering from phlegmonous inflammation of the right leg. While treating him, I noticed that the patient was also afflicted with hallux valgus on the right side.

After having obtained his consent, I performed, on October 30th, resection of the head of the first metatarsal bone, in strict accordance with the method recommended by Huster. After making a small longitudinal incision along the inner margin of the foot along the diseased portion of the metatarsal head down into the bony tissue, I lifted the soft parts *together with the periosteum* and the sheaths of the tendons from the surface of the bone and then decapitated the bone with the straight narrow saw.

My experience has led me to consider this saw as the instrument *par excellence* for such operations, especially for subperiosteal resections of the ankle-joint, providing a certain degree of skill is acquired by frequent trials on the cadaver.

Concerning the after-treatment, Dr. Hamilton and myself have employed the warm-water bath for the purpose of preventing the only dangerous complication, *viz.*, suppuration of the sheaths of the tendons and consecutive phlegmonous inflammation.

The method of superiosteal and subcapsular resection itself already avoids this danger and renders the permanent bath unnecessary.

In this case I still used the permanent bath on account of the patient's tendency to phlegmonous inflammation. But the patient complaining of pain while in the bath, and feeling better without it, I desisted after a few days from immersion, and ordered instead moist applications. Having left St. Francis Hospital soon after performing this operation, I was informed by my former assistant, Dr. Edebohls, that lint, fastened by adhesive plaster, had been applied to the wound, that an abscess had formed over a neighboring metatarsophalangeal joint, which was opened and soon closed.

The patient having fully recovered, was discharged with well-formed and perfectly useful foot.

151 AVENUE B, N. Y.

THE TREATMENT OF ABORTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the article on "The Treatment of Abortion," by Dr. Skene, in your issue of Jan. 23d, I notice that among the "mechanical means" mentioned for the purpose of removing the ovum, a manipulation has been omitted, which was first described by Dr. Hoening, of Bonn (*Scanzoni's Beiträge*, Vol. VII., 1873), and which I have had occasion to employ to my great satisfaction in several instances. Thinking it may be interesting and serviceable to your readers, as it was to me, and knowing the difficulties and dangers which usually attend the removal of the ovum in abortion by means of the fingers, forceps, or curette, I am induced to request a limited amount

of your valuable space to describe it. Hoening recommends to express the ovum, either entire or in part, if the fœtus be already removed, by means of bi-manual compression, two fingers of one hand being introduced into the vagina and passed as far up as possible into the fornix vaginae, and the other grasping the uterus through the abdominal parietes, thus firmly compressing the organ between the fingers of both hands and slowly and surely expelling its contents. If the uterus is anteverted or anteflexed, as is usual during the earlier months of pregnancy, the two fingers should be passed into the anterior cul-de-sac, or the corpus uteri may be firmly pressed against the symphysis pubis by the external hand alone (the bladder having been emptied); if the uterus is retroflexed, the two internal fingers go behind the cervix. The relaxation of the abdominal parietes in multiparæ (in whom, as has been statistically shown, most abortions occur), usually renders the seizure of the uterus by the external hand an easy matter. The facility and rapidity with which the expression of the ovum is accomplished, is, according to Hoening, surprising and gratifying, as also the absence of subsequent hemorrhage or puerperal trouble. The pressure in the uterus need not and never should be sufficient to do harm.

Before reading this paper, I happened to meet with a case of miscarriage, in which I succeeded in expressing the retained placenta by bi-manual compression. Since then, during the past summer, I employed the manipulation in two cases, both abortions in the fourth month, in consequence of retroversion, with the most complete success. Passing two fingers into the posterior cul-de-sac, and grasping the uterus firmly with the other hand from without, I immediately felt the uterine contents slip out towards the cervix, and pressed them entirely into the vagina by passing the two fingers behind the cervix forwards, towards the external os. Both ova were expelled into the vagina entire, the membranes of one of them rupturing as it left the os. Both women made easy and rapid recoveries.

Of course it is essential that the cervix be sufficiently dilated before the measure is attempted; in my two last cases I accomplished the dilatation, and at the same time controlled the hemorrhage by the introduction of the colpeurynter for several hours. The uterine contractions attending the dilatation of the os will generally loosen the adhesions of the ovum to the uterus sufficiently to allow of its easy expulsion.

The advantage of this *vis a tergo* over the introduction of the speculum, the forceps and the curette, to say nothing of the old method of passing the finger into the uterus, are obvious. I trust this communication may contribute to the general adoption of this most excellent practice.

PAUL F. MUNDÉ, M.D.

ANCIENT ART.—At a recent meeting of the Obstetrical Society of London, a cast was presented of an antique group representing the Circumstantial of Labor in very early times, taken from the original found at Golgos, in Cyprus, in a temple erected in honor of Baal, the supreme divinity of generative power, and Ashtoreth, that of productive power. The group consists of four figures, the mother reclining on a couch, an attendant at the head, and the nurse sitting at the foot of the couch with the new-born infant in her lap. It was probably made three hundred years before the Christian era.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The annual meeting of this Society will be held at Albany, Feb. 2, 3, and 4.

New Instrument.

A NEW GALVANIC PESSARY.

By H. T. HANKS, M.D.

THE instrument consists of alternate beads of zinc and copper strung on a copper wire, bent in the shape of an Albert Smith pessary. On the interior portion, instead of beads, rubber tubing covers the wire, otherwise the pessary would be too heavy.

I have used this instrument in the case of a young woman aged nineteen years, quite stout, unaccustomed to active physical exertion. She menstruated first at fifteen years; during the last four years only six times. Physical examination revealed uterus, normal size, low down in the first degree of retroversion. Patient had suffered from frequent attacks of headache and pain in the small of the back. This pessary was applied three months ago, since which time she has menstruated twice.

The beneficial effects of the Galvanic Stem Pessary have been recognized by such distinguished men as Simpson, Tait, and several of the leading gynecologists of the city. The advantages of this *new* pessary are as follows, viz. :—

- 1st. It is more easily applied.
- 2d. It causes less discomfort in its use to the patient.
- 3d. The acid secretion of the vagina has a more decided chemical action upon the beads than the alkaline secretion of the uterus.
- 4th. In amenorrhœa attended with slight retroversion or prolapsus, it not only stimulates the ovaries by its galvanic action, but at the same time retains the uterus in position.

149 LEXINGTON AVENUE, Dec. 22, 1874.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from January 17th to January 23d, 1875.

KINSMAN, J. H., Assistant Surgeon.—Assigned to duty at Fort Seward, D. T., until further orders. S. O. 9, Dept. of Dakota, Jan. 16, 1875.

HEIZMANN, C. L., Assistant Surgeon.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 13, A. G. O., Jan. 20, 1875.

MOSELEY, E. B., Assistant Surgeon.—Assigned to duty at Mobile barracks, Mobile, Ala. S. O. 4, Dept. of the South, Jan. 14, 1875.

SKINNER, J. O., Assistant Surgeon.—Leave of absence extended one month, with permission to apply to the Headquarters of the Army for a further extension of three months. S. O. 7, Mil. Div. of the Pacific, Jan. 12, 1875.

Medical Items and News.

VIVISECTION.—At a regular meeting of the Putnam Co. Medical Society held at Carmel, October 27th, 1874, the following preamble and resolutions were unanimously adopted:

WHEREAS, It is generally understood that an effort is being made by the Society for the Prevention of Cruelty to Animals to abrogate a clause of the law relative to vivisection, viz., "Nothing in this act shall be construed to prohibit or interfere with any properly conducted scientific experiments or investigations," therefore

Resolved, That this Society recognize the importance and necessity of experiments upon animals as a means of advancement in the knowledge of disease, its causes, and its cure.

Resolved, That we believe these experiments are conducted in conformity with the spirit of the law, and with due regard to the suffering and distress of the animals employed.

Resolved, That the suppression of physiological and pathological research by means of vivisection would interfere materially with our progress in medical science, and thus prove a great detriment to the medical profession, and to the welfare of mankind. Also,

Resolved, That we will put forth every effort in our power to preserve and perpetuate this law as it now exists.

J. H. BAILEY, M.D., Pres't.

MATTHEW A. BAILEY, M.D., Sec'y.

DISTRICT MEDICAL SOCIETY OF THE COUNTY OF HUDSON, N. J.—At the recent annual election of the District Medical Society for County of Hudson, the following were elected officers: For President, J. J. Prendergast; Vice-President, J. B. Burdett; Secretary, C. C. Young; Treasurer, W. R. Fisher, of Hoboken; Reporter, T. F. Morris. Delegates to State Society: B. D. Carpenter, L. R. Foiman, F. E. Nobile, R. F. Chabert, W. R. Fisher, J. J. Prendergast, D. L. Reeve, H. Michell, J. W. Hunt, J. H. Vondy.

FEMALE MEDICAL EDUCATION IN ENGLAND.—A school of medicine for women is about going into operation in London, with T. King Chambers as Professor of Practice; Berkely Hill, Professor of Surgery; and Mr. Crickett of Ophthalmic Surgery. Drs. Burdon Sanderson, Hughlings Jackson, W. L. Playfair and Professor Huxley are members of the Council. Dr. Austie held the position of Dean of the Faculty, and the last public act of his life was to apply for recognition of the school as a duly constituted teaching body.

A LICENSING BOARD IN TENNESSEE.—We hear, from rather doubtful authority however, that a bill has been introduced in the Senate of Tennessee providing for the establishment of a State Board of Physicians, to issue licenses to all the physicians practising in the State. It provides for the establishment in each grand division of the State of a board of regular physicians, who shall have authority to meet annually at Knoxville, Nashville, and Memphis, to grant licenses to physicians and fix the fee therefor, when the same are not already fixed by law; to prescribe a course of reading for those studying medicine under private instruction; to grant licenses to practice particular branches of medicine or to treat particular diseases, and to grant licenses to apothecaries. The bill also provides that physicians who practise medicine or surgery for fee or reward in violation of this act shall be liable

to an indictment and fine of five hundred dollars for the first offence, and imprisonment not to exceed three months for the second offence, the fine to go to the School Fund. Druggists violating the proposed law are to be fined from five hundred dollars to one thousand dollars. Physicians now practising are exempt from the provisions of the bill, and those of any other than the regular school will be allowed to practice upon their diplomas.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY. Seventh Annual Meeting, Newport, R. I., July 15, 1874.—This pamphlet of one hundred and twenty-nine pages, contains a "Report on the Progress of Otology," by H. Burnett, M.D., and J. C. Blake, M.D., the former reporting on Anatomy and Physiology, the latter on Pathology and Therapeutics. Drs. Clarece, J. Blake and Arthur Mathewson were elected to prepare a similar report for the coming year. The papers presented to the Society and published in the transactions were: "Ultimate Forms of Granulation Tissue in the Ear," by Dr. A. H. Buck; "Case of Otitis Media Purulenta, with Sinus opening into the Pharynx," by Dr. A. Mathewson; "A Case of Aural Polypus, having a Cartilaginous and Osseous Base," etc., by Dr. O. D. Pomeroy; "Mechanical Value of the Distribution of Weight in the Ossicula," by Dr. C. J. Blake; "Perforations of the Membrane of Sharpnell in Purulent Inflammation of the Middle Ear," by the same author; "Chronic Discharge from the Tympanum, with Perforation of the Membrana Flaccida posteriorly," by Dr. C. H. Burnett; "Case of Irritation of Chorda Tympani. Paralysis of Facial, Polypoid Growth upon the Membrana Tympani, Peristitis of the Malleus and adjacent Bony Texture," by Dr. H. D. Noyes; "Neuralgia in and about the Ear," by Dr. J. Orne Green; "A Case of Chronic Suppurative Inflammation of the Inner Ear," reported by Dr. David Webster; "Tenotomy of the Tensor Tympani Muscle, done posteriorly to the Malleus Handle, with Guber's Instrument, with Cases," by Dr. O. D. Pomeroy, and "A Case of so-called Mènière's Disease," by Dr. C. H. Burnett.

GIANT IRISHMAN.—An Irishman seven feet eight inches high died recently in Scotland.

BOTANICAL GARDEN IN BALTIMORE.—Baltimore is to invest \$50,000 in a botanical garden.

LIVINGSTONE'S HUMERUS.—The Chicago Medical College has obtained a plaster cast of the humerus of the great missionary, showing the famous false joint caused by the jaws of the lion.

DR. WILLIAM RUTHERFORD, recently of King's College, London, has been appointed to the chair of physiology in the University of Edinburgh, in place of Professor Bonnet, resigned.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, Feb. 1.—Medico-Chirurgical Society, Morrisania Medical Society, N. Y. Neurological Society, Pathological Society of Brooklyn.

Tuesday, Feb. 2.—Medical Society of the State of New York, at Albany, N. Y.; Obstetrical Society, East River Medical Association.

Thursday, Feb. 4.—N. Y. Academy of Medicine, "Pneumonia, its Prevailing Type and Treatment," Discussion by Professors A. Clark, Flint, Thomson, Peaslee, Leaming, and others.

Friday, Feb. 5.—Medical Library and Journal Association. "On Water Poisoning as a Cause of Disease," by Thomas H. Bailey.

Original Lecture.

ON THE PATHOLOGY AND ETIOLOGY
OF MORBUS COXARIUS.

By LEWIS A. SAYRE, M.D.,

PROFESSOR OF ORTHOPEDIC AND CLINICAL SURGERY IN THE BELLEVUE
HOSPITAL MEDICAL COLLEGE.

(Reported for the MEDICAL RECORD.)

LECTURE II.

GENTLEMEN:—We next pass to the study of the pathology and etiology of morbus coxarius. Under the head of pathology we shall describe the changes that take place in the tissues of the joint during the earliest changes of the disease, leaving the changes which take place in the more advanced stages to be considered in connection with the symptoms to which they give rise.

First—The disease may begin as a synovitis.

Second—It may begin in a rupture, partial or complete, of the ligamentum teres; thereby interfering with the nutrition of the head of the femur.

Third—It may begin from rupture of some of the little blood-vessels which are situated in the bone just beneath the cartilage of incrustation. This may occur either upon the head of the femur or at some point in the acetabulum, and results from blows, jumping, or anything which may produce a sudden concussion of these articular surfaces. These three conditions require special consideration.

First, then, of synovitis. Inflammation of the synovial membrane of the hip-joint may be produced in the same manner as it is produced in any other joint of the body, but it is almost always the result of exposure to sudden changes of temperature after violent exercise, such as skating, racing, jumping, playing at football and other movements that over-exercise the joint.

When the synovial membrane becomes inflamed effusion of fluid into the cavity of the joint always takes place. The synovitis may be subacute in character, and attended by the effusion of only a small quantity of fluid, but not followed by disintegration of the tissues of the joint; or the same degree of inflammation, in some cases, may be followed by complete disintegration of the joint structures.

Again, the synovitis may be very violent, be accompanied by intense pain and the effusion of a large quantity of fluid, and make rapid progress towards destructive changes within the joint. When the joint becomes distended with fluid there will be present a peculiar deformity, which we shall fully describe when we come to study the symptoms of hip-joint disease. Of course the synovial membrane sooner or later becomes involved as do the cartilages, ligaments and bones, no matter how the disease begins; but that there are cases of hip-joint disease which have their commencement in a synovitis I am fully convinced. When the synovial membrane becomes involved *secondarily* the same deformity will be produced as when it is the *primary* affection, which will be more fully studied hereafter.

Second—Any violent straining of the ligamentum teres, such as may be caused by forcibly stretching apart the legs, or by other violent exercise which gives motion to the joint to the extreme limits, may partially or completely separate it from any of its attachments to the bones. It is most likely, however, to be sepa-

rated from its attachments to the head of the femur. When such an accident occurs the vessels which supply the head of the femur are destroyed, and necrosis follows as the result of interference with its nutrition. Secondary changes soon occur in the cartilages and synovial membrane, and the case goes on, if not relieved, to the development of hip-joint disease in its worst form.

Third—When the disease begins in the blood-vessels in the articular lamella, it first appears as an extravasation or "blood-blister" at some point. This is the nidus or starting-point, and if the damage done is detected at the time of the infliction of the injury, *rest alone*, if continued for a sufficient length of time, will probably bring about a favorable termination in a great majority of instances. But the damage done not being detected, and in many instances not even suspected, the rest necessary is *not insisted* upon at the proper time; consequently the disease is slowly developed, and frequently is not distinctly pronounced until long after the accident that has caused the trifling damage to the blood-vessels, and given rise to so much trouble, has been entirely forgotten.

A pinch of the skin producing a "blood-blister," in slight extravasation of blood within the cellular tissue, is of common occurrence, and is of no great importance. If let alone, it will soon be absorbed; or at most, if you let the fluid out and do not irritate the wound, it will soon get well. But suppose, even in this most trifling injury, that, instead of giving it rest and time to heal, you constantly scratch it with a rusty nail; you will produce a sore that will last as long as the irritation is continued. This is a parallel case with a joint that is exercised after concussion or a blow or wrench that has produced an extravasation of blood from the tufts of blood-vessels already referred to.

Now, while I believe that this disease begins in one of the three ways mentioned, I would not have you understand that the disease progresses very far, without involving all the structures entering into the composition of the joint.

For instance, when the disease begins as a synovitis, the cartilages, bones, and ligaments sooner or later become involved. So when the disease begins in destruction of the ligamentum teres, partial or complete, the same consequences ensue, and the same is true when the disease begins as an extravasation of blood in the manner described.

I do not believe, however, that the disease ever begins in the cartilages of the joint, for the reason that these structures contain neither blood-vessels nor nerves. Necrosis occurs *secondarily* in the cartilages on account of the loss of nervous and vascular supply to the tissues upon which they depend for nutrition.

This, according to my view, constitutes the pathology of this disease at its very beginning. There are other and very important pathological changes that occur as the disease progresses; but inasmuch as certain symptoms, such as certain positions which the limb assumes, are directly dependent upon these pathological changes, I shall consider these in connection with the symptoms to which they give rise. We shall now pass to the study of the subject of causation.

ETIOLOGY.

Almost all surgical authorities agree that morbus coxarius is invariably the result of a contaminated constitution; in other words, that it is essentially strumous in its origin. This has been the universal opinion, and the doctrine has descended from teacher to student, and is still extant among the majority of surgical practitioners. It has been so often taught

and enforced by frequent repetitions, that nobody considered it worth while to question its truth; but nearly all have taken it for granted, that an assertion so positively made and universally accepted must be based upon mature investigation. When I first entered the profession I accepted this doctrine taught by our fathers, but must confess that I never was fully satisfied with regard to its correctness. Now, while I revere the labors of those great men in the advancement of scientific investigation, I must be permitted to question what is questionable, and to doubt what is doubtful.

Examination of the cases which have presented themselves to my notice since that time has convinced me that the cachectic condition so often seen is the result and not the cause of the disease; for very many of the patients in the earlier stages of the disease have possessed all the appearances of robust health, and in all those cases in which the disease has been cured by nature's method, the patient, subsequent to the cure, has been hale and hearty. I do not suppose there is a person in this room who cannot call to mind some old fellow with a shortened hip, perfectly ankylosed, who yet has a ruddy face, a good healthy complexion, and is a vigorous, robust old man. If he had had scrofula in his system, it would have remained there, and when his hip had recovered the man would have been a miserable old fellow after all. The very fact of his becoming a vigorous, robust man after going through all the exhausting effects of hip-joint disease proves, in my judgment, that the disease is not of constitutional origin.

The additional fact that, in so many cases, the joint has been excised when the patients have been, apparently, at the point of death, and after the removal of the dead bone have become vigorous, strong persons, is good evidence that the disease is not constitutional. Then there is the still stronger fact that, by treating the disease locally without reference to constitutional taint, we obtain perfect results, so much so that the patients recover with perfect motion and without the slightest deformity, which is the best proof in the world that the disease is essentially local in character.

Another fact worthy of consideration is that a very large proportion of cases of the disease occur in children, while the scrofulous condition is by no means so restricted.

I have unfortunately recorded only a small part of the cases which have fallen under my observation, but 330 cases have been fully entered upon my record, and of these, 250 were under the age of fifteen years, and 80 were under the age of five years. Similar results have been obtained by other gentlemen who have collected statistics upon this point.

Now, it is not necessary for me to prove that adults are nearly as liable to be affected with scrofulous diseases as are children, the less number of cases seen being due to the fact mainly that these sickly children are very liable to die before reaching adult life. If, therefore, we still adhere to the scrofulous theory, we are forced to conclude that the diathesis, which in childhood develops itself in joint disease, manifests itself in some other way after puberty. This I cannot believe. Childhood is the age of restless activity, and out of the hundreds of cases in which I have taken the trouble to trace their history I have found that the immense majority, I may safely say seventy-five per cent., have occurred in the most vigorous, robust, wild, harum-scarum children—boys who take their chances of danger, who run races, climb over fences, jump out of apple-trees, kick their playmates down stairs,

ride down balusters, and are generally careless and reckless.

On the other hand, the adult does not place himself in the position in which he can receive so many blows or falls as the active child does, and furthermore he immediately notices the effects of his injury, and takes precaution against its development into serious trouble. The child, however, knows nothing of results, and unless the pain from the injury is great will probably fail to complain of it, and soon forget it altogether. This, I believe, is the true reason why so many more cases of joint disease are seen in children than in adults.

I do not wish to be understood as saying that scrofula is a *preentive* of disease of the hip-joint, as has been asserted concerning my teaching. All things considered, a smaller amount of injury will produce the disease in one of these miserable sickly children than in a healthy, robust child. But the sickly, scrofulous child who clings to his mother's apron does not run the risk of getting hurt as do these active, restless children; consequently the majority of cases occur among the active and robust.

From what has been said, you have probably already drawn the inference that I regard the disease as one almost invariably due to a *traumatic* cause, and not dependent upon some constitutional taint. To what has already been said upon this point we may add the positive evidence of statistics.

Of the 330 cases alluded to above, *traumatic* cause was assigned by the patient or the parent in 228; while in 102 cases the cause was recorded as unknown.

In 243 cases the previous general condition of the patient was good; in 42 cases it was bad; and in 45 cases it was unrecorded. These figures are taken from the notes of my own fully recorded cases. Cases not fully recorded have been rejected in making these statistics.

Now, the cases in which the previous condition was bad, together with those in which it was unrecorded, make up less than 27 per cent. of the whole; and it is possible that very many of those had a traumatic origin that had been overlooked or forgotten, owing to the insidious manner in which the changes had come on.

My own clinical observations with reference to this point stand by no means isolated. The same observations have been made by other surgeons, both in this country and in Europe.

It generally requires a very close examination to find out the cause, since the disease does not usually follow the injury immediately; but often first manifests itself weeks and even months after the accident that has given rise to it has occurred; so that the patient and his friends naturally enough forget the accident and the connection with the disease until especially reminded of it in the investigation.

So much, gentlemen, for the pathology and causation of hip-joint disease, and now we are ready to begin the study of its symptoms.

THE USES OF ASSOCIATION MEETINGS.—Dr. Max Muller, in a recent inaugural address, says that the uses of association meetings are twofold: "1. They enable us to take stock, compare notes, to see where we are, and to find out where we ought to be going. 2. They give us an opportunity, from time to time, to tell the world where we are, what we have been doing for the world, and what in return we expect the world to do for us."

Original Communication.

CLINICAL NOTES ON SOME COMMON DISORDERS OF THE NERVOUS SYSTEM.*

By ALFRED L. CARROLL, M.D.,

MEMBER OF THE N. Y. SOCIETY OF NEUROLOGY AND ELECTROLOGY;
CONSULTING PHYSICIAN TO THE S. R. SMITH INFIRMARY, ETC.

IN obedience to the flattering request of this Society, I shall endeavor briefly to describe the more prominent clinical features of a few of the forms of nervous disease most likely to be met with in general practice; and it much of what I shall have to say prove quite familiar to the experience of my hearers, my excuse must be that even the commonest of these forms of disease are very inadequately depicted, if mentioned at all, in the ordinary medical text-books to which the busy practitioner refers for information; the literature of the subject being relegated to special treatises, or scattered throughout various periodicals and isolated monographs.

The oftenest-seen nervous disturbances are those arising from cerebral hyperæmia, or its opposite, anæmia, before any actual structural lesion has occurred; and the importance of recognizing these conditions is evident when we consider that the gravest organic degenerations find their starting-point in impairment of nutrition, which, in its turn, depends on the quantity and quality of the blood-supply. As regards the latter (the qualitative condition), I am fully persuaded that very many of the organic diseases of the nervous centres, now considered as the exclusive property of specialists and electro-therapeutists, are of toxæmic origin (using the word toxæmic in its largest sense), and will ultimately revert to their fitting place within the range of general pathology and rational medicine. We already know how many nervous maladies are of syphilitic, scrofulous, or lithæmic origin; we often see the action of malaria in producing neuralgia, intermittent paralyses, and other functional, if not organic, nervous derangements; we can frequently trace degenerative textural changes to their etiological source in chronic alcoholism; and, aside from such specific contaminations, it seems not unreasonable to suppose that any diminution of the nutritive properties of the blood would be most apt to show its effects in structural degeneration of the nerve-cells, which, being the most delicately organized of tissues, require the most elaborately-prepared pabulum; and more particularly should we look for this where hereditary or acquired influences were at work to depress the vitality of the nervous system.

To return from this digression: in speaking of cerebral hyperæmia I am not now referring to the quasi-acute attacks of congestion with which every practitioner is familiar, and which in their most pronounced form present apoplectic symptoms; but to a more insidious chronic condition which may endure for months without attracting professional attention. There is—at all events in the earlier stages—rather an exaltation than an actual impairment of the cerebral functions; the patient finds more or less difficulty in concentrating his thoughts upon any one subject, simply on account of the confusing multiplicity of ideas which arise with simultaneous spontaneity; the

same functional over-activity of the brain commonly keeps him awake at night; he frequently suffers from headache, or oftener from a sensation of intracranial pressure or fulness not amounting to actual pain. In connection with this cerebral hyperæmia, and probably as a consequence of the brain receiving more than its share of blood, the digestive processes are usually sluggish; but, in the stage which I am describing, the patient seldom feels seriously alarmed about himself. He is often, indeed, in rather higher spirits than natural, the emotional as well as the ideational processes being accelerated; at other times, however, this emotional excitability may show itself in increased peevishness of temper. The condition thus briefly sketched is one very often met with, the diagnosis being in most instances sufficiently obvious; its early recognition and treatment, however, may avert grave results.

Scarcely less common is the opposite state of chronic insufficiency of cerebral blood-supply, which, though often dependent on general anæmia, may unquestionably exist as an idiopathic disorder. Although, as might be supposed *à priori*, the symptoms of cerebral anæmia are in many respects in direct contrast to those of hyperæmia, yet there are exceptional cases in which it may be a matter of some difficulty to distinguish between the two with certainty. As a general rule, it may be said that anæmia is characterized by mental depression with deficiency rather than excess of ideational processes. Instead of the incoherent activity and emotional exaltation which in greater or less degree accompany hyperæmia, we have listlessness and despondency. In brief, the type of exaggerated hyperæmia is mania; that of extreme anæmia is melancholia; and in the less pronounced forms of these conditions the mental symptoms respectively approach more or less nearly to such types. Drowsiness is an almost invariably concomitant of anæmia, but, by a seeming contradiction, the patient is often annoyed by wakefulness on lying down at night, a phenomenon ascribed by Dr. Hammond to the gravitation of blood into the brain in a recumbent posture inducing "comparative hyperæmia," but which I should rather attribute to defective nutrition with consequent irritability of nerve-tissue; for, in the first place, the head is usually sufficiently elevated by the pillows in bed to counteract partially the attraction of gravitation, and, in the second place, in my experience, at least, the anæmic vigil is almost peculiar to the night time, with but little regard to posture. I have seen patients in this condition who could doze throughout the day, not only sitting, but lying on a sofa with the head as low as it would be in bed, but who, on retiring for the night, at once became morbidly wakeful. It may, of course, be argued that in such instances the exhaustion following a restless night compels the diurnal sleep, while this in turn increases the nocturnal wakefulness, but I am inclined to believe that nervous apprehensiveness of losing the natural repose plays an active part in banishing slumber. The headache which accompanies anæmia is usually circumscribed in the vertex and neuralgic in character, and not infrequently associated with neuralgias in other situations. There is sometimes vertigo, and usually dizziness, especially on rising from a recumbent to an erect posture. Tinnitus aurium is commonly present, and in the majority of cases muscæ volitantes are seen. If the general anæmia be marked, we shall find, in addition to facial pallor and the almost pathognomonic dead-whiteness of the conjunctiva, the well-known disturbances of accentuation of the heart-sounds, with perhaps basic murmur and "venous

* Delivered by request before the Richmond County Medical Society, December 2, 1874.

hum" in the cervical vessels; but these belong to a more advanced condition than that of which I am now speaking. In nearly all instances, however, there may be observed evidences of an enfeebled and irregular circulation. I have not alluded to ophthalmoscopic inspection of the retinal vessels as a means of diagnosis, partly because the general practitioner seldom has time to make himself expert in such examinations or opportunity to apply them to the class of patients just described; partly because—however valuable the ophthalmoscope may be in the detection of other central nervous lesions—considerable variations in the intra-ocular circulation may occur within the range of health, or be dependent on local conditions.

Whether the condition described by some writers under the title of cerebral exhaustion be primarily due to functional enfeeblement of the nerve-cells, irrespective of circulatory alteration, or the result of intra-cranial anæmia, is a question still, I think, *sub judice*.

The brief time at my disposal precludes consideration of the treatment of these morbid states, which must be chiefly hygienic (I exclude, of course, the cases in which the cerebral disorder is merely symptomatic of an actual local lesion, or of organic disease in other viscera, as the heart or kidneys). As regards two remedies very often prescribed—namely, hydrate of chloral and bromide of potassium, it should be borne in mind that both reduce the cerebral circulation, and hence, while they may be of great service in hyperæmia, they should be avoided in anæmia. In the latter state, in addition to chalybeate tonics and nutriment, alcoholic stimulants are sometimes useful; but I need scarcely say that they should be prescribed with caution and, especially in the case of low-spirited females, in fixed doses.

Paralytic conditions constitute a large proportion of the nervous diseases encountered in general practice, and oftentimes present difficulties in the way of diagnosis. For convenience of description, paralytic conditions of intra-cranial origin may be divided into those which are sudden and those which are gradual in their access, though, strictly speaking, there is little pathogenetic difference between the pressure of a hemorrhagic clot and that of a slow-growing tumor. Of the sudden paralytic conditions, the most familiar examples are those which were formerly grouped together under the generic head of apoplexy, but which are now known to arise from one of several different causes, their common symptoms being loss of consciousness and hemiplegia. The most frequent of these causes are: extravasation of blood, rapid local congestion, and the obstruction of an artery by the lodgment of an embolus detached from the heart. At the time of the seizure, it is impossible, in the majority of instances, to decide which of these conditions obtains. It has been asserted that in congestive apoplexy the palsy is usually not confined to one side of the body, and that stertor is seldom present; but although in the absence of post-mortem facts it is impossible to deny the existence in any given instance of some small peripheral extravasation, to the pressure of which the brain-substance may soon accommodate itself, it is nevertheless certain that cases frequently occur of sudden hemiplegia with snoring coma, which the rapid subsidence of the symptoms apparently warrants us in ascribing to local congestion. Equally untrustworthy are any diagnostic signs related to the appearance of the iris; for in hemorrhagic apoplexy the pupil may be either contracted or dilated, according to the seat and degree of lesion. In most instances, however, we may learn

that the congestive apoplectic seizure has been preceded by symptoms of cerebral congestion.

In embolism, consciousness is generally, though not always abolished, and its recognition in most cases must depend on knowledge of the patient's previous history as to cardiac disorder. Inquiry into antecedent symptoms will usually enable us to exclude the apoplectiform seizures which occasionally supervene upon epilepsy; the same remark applying to the sudden palsy which (sometimes without coma) arises from softening of the brain.

The so-called serous apoplexy is, as a rule, marked by progressive deepening of symptoms rather than instantaneousness of seizure, but if the effusion be very rapid it may be undistinguishable from cerebral hemorrhage.

A circumstance which may at first sight occasion some confusion is that in extensive cerebral hemorrhage a state of shock may precede the development of the true apoplectic coma. In the case of a gentleman whom I saw some months ago almost immediately after the first occurrence of extravasation, this shock was so profound as to amount nearly to collapse: there were waxy pallor of the face and lips; coldness of the surface; shallow, feeble, sighing respiration; a scarcely perceptible, fluttering pulse; all the appearances, in fine, which follow severe surgical injury. This possibility should be borne in mind as simulating syncope or hysterical coma. It is only, however, at the moment of attack that any of these perplexities are likely to occur; the character of the lesion being generally pretty clearly defined by the subsequent phenomena.

In some cases of rapid and extensive injury to the brain substance (as from hemorrhage of considerable amount) we may notice for a longer or shorter time a turning of the eyes away from the palsied side. There is neither the divergent squint of paralysis of the third pair of nerves, nor the convergent strabismus significant of incapacitation of the sixth; the ocular axes remain parallel, but they (and in many instances the head also) are turned to a considerable angle from the mesial plane. This phenomenon, according to Hughlings Jackson, betokens injury of the brain far above the origins of the nerves apparently implicated—involving the higher centres which preside over associated movements. To use Dr. Jackson's phrase, "there is loss of a chord, not loss of a few notes." He affirms also that such lateral deviations occur with superficial lesions, as from meningeal hemorrhage, etc., or with crippling of other parts of the nervous system, notably of the *crus cerebelli*.* In speaking of localization, it is, of course, understood that the hemiplegia itself shows the corpus striatum to be pressed upon; but this pressure may be caused by an adjacent lesion as well as by an effusion into its proper substance, and we not unfrequently find hemiplegia produced by a clot situated at some distance from the corpus striatum. As an apparent exception to the rule that paralysis of one half the body arises from direct or indirect compression or disorganization of the corpus striatum, may be noted the hemiplegia (usually of the right side) attending the sudden lodgment of an embolus in the middle cerebral artery. Here the palsy cannot be accounted for by compression, and the only explanation to be given of it is by surmising an arrest of function of the corpus striatum, due to the cutting off of its blood-supply, which is chiefly derived from the middle cerebral artery. This view is supported by the fact that embolism sometimes occurs in this vessel

* Brit. Med. Journal, July 25, 1874.

without causing hemiplegia (in which case we may suppose the obstruction to be beyond the origin of the branches going to the striated body), and, furthermore, that embolic hemiplegia, if it persist after the time requisite for the establishment of collateral circulation, is traceable to anemic softening.

In most instances in which we are consulted, however, paralysis has been of some duration, and the question presented to us is to determine the nature and locality of the lesion from our knowledge of physiological anatomy, and an inquiry into the history of the case.

The first thing to be ascertained is whether the palsy be of cerebral origin, and this, even in the case of hemiplegia, in the absence of marked facial paralysis, or implication of some of the cranial nerves, may not always be an easy task, since unilateral lesion of the upper part of the spinal cord may possibly be the cause. Such spinal hemiplegia is said, by some authors, to be distinguishable by its involving the thoracic and abdominal muscles, leaving the mental faculties unimpaired, and being usually attended with anaesthesia; but none of these signs are unailing. The escape of the respiratory muscles, in most examples of cerebral hemiplegia, is explained by Broadbent's hypothesis: that paired muscles, which habitually act together, are both represented in each side of the brain, and hence both receive their motor-stimulus even when one side of the brain is crippled. Moreover, we know that the more automatic muscles are the last to suffer from paralysis and the first to recover. But in the gravest brain lesions the respiratory movements of the palsied side are often affected. On the other hand, hysterical paralysis is commonly accompanied by anaesthesia.

Great aid in diagnosis may be derived from the application of electricity in many doubtful cases of paralysis, if the requisite apparatus be at hand. Thus, as a rule, in paralysis of cerebral origin, the contractility of the affected muscles under the induced or faradic current is unimpaired; in spinal paralysis this contractility is lessened; whilst in hysterical paralysis electro-contractility is normal, but sensibility to the current is diminished. As a galvanic battery seldom forms part of the general practitioner's office furniture, I need not refer to the diagnostic uses of this form of electricity in distinguishing some cases of peripheral from central paralysis.

To return to our immediate subject, it may be assumed that in at least ninety-nine out of every hundred cases of hemiplegia the lesion is in the brain, and it remains for us to discover what it is and where it is. That it arises from either compression or disintegration, affecting the corpus striatum, optic thalamus, or pons varolii, we already know; but the disintegration may be caused by hemorrhagic laceration, or by softening following embolism, or by abscess, or by so-called idiopathic ramollissement (which is probably eight times out of ten from anaemia, and the other two from toxæmia), whilst the compression may come from a clot or a neoplastic growth, as tubercle, cancer, syphilitic gumma, fibroid tumor, or ossific deposit, or from aneurism or hydatids.

If the palsy have been of sudden occurrence, I have shown how a knowledge of its mode of seizure may help us in determining its cause; if, on the contrary, its access have been gradual, we have usually to decide between softening and some progressive source of pressure. If we learn that after an apoplectic attack rigidity of the affected muscles took place, we may infer that inflammatory action, with subsequent disintegration, set in around a hemorrhagic clot. In the

absence of such inflammatory action, there is commonly a gradual amelioration in the symptoms, both mental and physical, of cerebral hæmorrhage in non-fatal cases; whereas in hemiplegia from acute softening (which, as has been said, may occur in some instances without premonitory indications) little, if any improvement is noticed, the paralysis persisting, and the mind being permanently enfeebled, whilst the muscles are flaccid and unresisting.

In chronic softening, there is usually a very insidious weakening of the intellectual faculties manifesting itself first, in want of memory, especially of recent events. The patient may remember, in detail, the occurrences of bygone years, but forgets those of the current day. With this, in the earlier stages, may be noticed irritability of temper, perversions of cutaneous sensibility, vertigo, headache of a dull, persistent character, often nausea and vomiting, and hemiplegia is ushered in by muscular debility, and partial paralysis of single facial muscles. As the disease advances convulsions are of frequent occurrence.

Abscess may generally be distinguished from softening (which in some respects it simulates) by its more rapid course, its average duration not exceeding a couple of months, and by the circumstance that convulsions usually precede paralysis. Moreover, we can sometimes obtain a clue from the history of some injury to the head or the existence of aural disease. It should be remembered, however, that a few cases have been recorded of large cerebral abscess proceeding to a fatal termination unattended by any marked mental or bodily disturbance. Or, again, an abscess which has reached a certain size without much functional derangement may produce an apoplectic seizure by its rupture.

The symptoms induced by a tumor vary according to the slowness or rapidity of its growth as well as its situation. A prominent characteristic in nearly all cases is deep-seated, localized headache, aggravated at intervals as new nerve-tracts are irritated by the augmenting encroachment. In proportion to the rate of growth, and in certain situations, the evidences of irritation preceding the paralysis caused by profounder pressure will be more or less marked, some cases being accompanied by repeated epileptiform attacks, whilst in others palsy slowly supervenes without convulsions at any time. In some examples the brain accommodates itself to the pressure, and we find an apparent amelioration of the symptoms, to be followed by their renewal as the tumor enlarges. In addition, there are ordinarily vertigo,* impairment of special senses, notably of vision, and other cerebral symptoms (seldom, however, attended by mental decrepitude), long prior to the advent of paralysis, which in its turn often affects, as in the case of abscess, the facial or ocular muscles before it crawls on to hemiplegia, or may even be confined to the former. In rare instances there are only convulsive symptoms without paralysis, and in still rarer ones the motor ganglia may escape pressure and a tumor may attain great size in one of the hemispheres without occasioning any symptom whatsoever.

As a strongly marked example of cerebral tumor, some interest may attach to the following case:

J. B., aged 53, about four years ago began to suffer from severe headache, which was better and worse at times. This was followed by epileptic fits at varying

*Vertigo having been spoken of as an early indication of several cerebral affections, it may be well to state that at a recent meeting of the Clinical Society of London (*Brit. Med. Jour.*, Oct. 31, 1874), Mr. Brudenell Carter and Dr. Hughlings Jackson adduce cases showing that this symptom, with others simulating brain-disease, may be caused by over-trained convergence of the eyes in short-sighted persons reading much without spectacles.

intervals and partial paralysis. The patient has now left-hemiplegia, divergent squint of the left eye with dilatation of left pupil, constant headache with occasional sharp exacerbations. Manner morose, but intellect not materially impaired. Sensation but slightly lessened. Epileptiform attacks occur with varying frequency. After an aggravation of the headache, these attacks, convulsing the unparalyzed limbs, will take place several times a day, their number gradually diminishing until several days elapse between them; they are not followed by the profound comatose sleep of ordinary epilepsy. Here there is evidently a tumor in the right hemisphere, the pressure from which has slowly encroached upon the corpus striatum, involving also the origin of the third nerve. The convulsions of the sound side may be explained by supposing that from time to time as the tumor enlarges an irritative squeezing of the left half of the brain takes place, to which after a while the tissues gradually become accustomed.

An instance of what I believe to be a new growth of a different sort was recently shown to me by my friend Dr. C. H. King, in the Seamen's Retreat Hospital, the principal features of which I may briefly recite from memory: The patient, a sailor of middle age, first came under his care some eighteen months ago, for facial neuralgia affecting the upper two branches of the right fifth nerve. This was relieved by treatment; but after about eight months he returned with a recurrence of the neuralgia, accompanied by deep-seated headache. Again an improvement was effected and he left the hospital; but after another similar interval, presented himself with hemiplegia, which had slowly supervened. The right side of the face, previously neuralgic, was now palsied, and with it the right side of the body; there had been, if I remember rightly, imperfect closure of the right eyelid, but there was no ocular deviation nor inequality of pupil. Hearing on the affected side was impaired. Speech not affected. Sensation somewhat diminished. No convulsive phenomena.

This history points, I think, to a new formation of very gradual development, the beginning of which made sufficient pressure on the fifth nerve to cause the neuralgic manifestation. Pain in a sensory nerve is significant of lowered vitality; anaesthesia, of abolition of function.* As the growth increased, deep headache was superadded, and the slowly augmenting pressure—too gradual to excite convulsive movements—ultimately extended to the corpus striatum and in less degree to the optic thalamus. The fact that the palsy is not complete—being rather paresis than paralysis—seems to show that the lesion does not involve the substance of the ganglia, but presses on their periphery only; its probable situation being the posterior part of the middle lobe of the left hemisphere. Although I am no believer in the exact localization of the faculty of articulate language in the third left frontal convolution, experience has taught that in lesions involving the left anterior lobe or the adjacent

parts bordering on the fissure of Sylvius,* right hemiplegia is commonly accompanied by aphasia.

Tracing the morbid indication from before backwards, we find that the third and fourth nerves escaped, as well as the sixth, the fifth nerve being the first affected, and this, seemingly, at some distance from its origin, since its lower division and its motor filaments remained intact. When I saw the case the seventh nerve was chiefly implicated and the slight affection of the portio mollis seemed to mark the posterior boundary of the intra-cranial palsy. Had the lesion involved the pons varolii we should probably have had the rare symptom of "crossed" paralysis (the facial palsy being on the same side as the cerebral injury and opposite to the affected side of the body) from the seventh nerve being crippled after its decussation with its fellow of the other side; in other words, a solution of continuity on the left side of the brain below this point really affects the facial nerve-fibres which come from the right side. If a lesion in the pons be seated at the level of this decussation, so as to involve both facial nerves, it may occasion the curious complication of bilateral facial palsy with bodily hemiplegia.

In all cases of this sort, however, our efforts to determine the precise seat of the morbid process are uncertain, since it is to be borne in mind that pressure from a distant lesion may be transmitted through intervening tissue to the points where its action become manifest. For example, in a case which I saw in consultation some three years ago, in which hemiplegia was complete and hemi-anaesthesia very marked on the left side, the autopsy showed the corpus striatum and optic thalamus to be structurally sound, the lesion being situated near the surface of the anterior part of the middle lobe of the right hemisphere. In the hasty sketch given of the patient before referred to (whom I had not an opportunity of examining very thoroughly) I do not, therefore, intend to assert a positive diagnosis, but merely to indicate the method of investigation to be followed.† Before leaving the subject of cerebral tumors, let me add that the prognosis in such instances is hopeless unless they be of syphilitic origin, for which reason it is advisable to give the patient the benefit of any possible doubt by the tentative employment of antisyphilitic treatment.

In the examination of almost all forms of cerebral organic nervous disease, much assistance may be afforded by the ophthalmoscope and other instrumental aids in diagnosis, but I have purposely refrained from considering these, wishing to deal only with the indications observable by the general practitioner's unaided senses.

I should have liked to say something of paralyzes of spinal or peripheral origin, as well as of other pathological conditions of the nerve-centres, such as sclerosis with its diverse but clearly-defined manifes-

* The younger Dax found reason, from numerous autopsies, to assign the organ of speech to the anterior and exterior part of the left middle lobe.

† My examination of this case on which the above remarks were based, was made in September. I now find that the patient has of late been subject to frequent convulsive seizures, with occasional paroxysms of almost maniacal excitement. The paralysis is much less marked than when I first saw him, the facial palsy having nearly disappeared. The motion of the right arm is greatly improved, but the right leg is still palsied. Catheterism is required from time to time—not so much, as Dr. King states, on account of the patient's inability, as of his unwillingness, to void his urine, which he passes voluntarily at some times, and at others retains until artificial evacuation becomes necessary. There is no aphasia nor difficulty of articulation; the patient answers questions and, during his excited moments, sings much. A long interval, however, elapses between a question addressed to him and his reply—sometimes several minutes, and his intellectual condition is one of dementia. Here the motor tract has apparently become gradually accustomed to the pressure which formerly impaired its function, and the brunt of the lesion is borne by the peripheral gray substance.

* Let me parenthetically suggest that tremor is, in the motor tract, analogous to neuralgia in the sensory, *i. e.*, an indication of lowered function (unstable equilibrium) of motor-cells not otherwise diseased. In cerebro-spinal sclerosis, for example, the characteristic tremor may be caused by a sclerotic patch crowding the unaffected motor-elements in its vicinity without quite paralyzing them. The function of the actually sclerosed portion is abolished; the tremor betokens depressed function of adjoining nerve substance. This may account for the apparent amelioration of the latter symptom sometimes obtained by galvanization, or other agents in cases of sclerosis, although the essential part of the malady defies our skill; our remedies really acting only on the texture which preserves its structural integrity. *Mutatis mutandis*, the same explanation applies to the neuralgic pains attending posterior spinal sclerosis (locomotor ataxia) and their relief by electrization.

tations; but I find that I have already exceeded all reasonable limits, and must apologize for trespassing too long upon your patience.

Progress of Medical Science.

TOTAL EXFOLIATION OF THE MUCOUS MEMBRANE OF THE BLADDER WITH RETROFLEXION OF THE GRAVID UTERUS.—The subject of this accident was a woman, thirty-six years of age, previously healthy, and who had borne three children, without any unusual symptoms. Dr. Brandeis, of Louisville, who reports the case, says that when he was called to her she had been suddenly seized with severe pain in the hypogastrium, and was unable to void her urine, in spite of violent straining. There was swelling and dulness on percussion extending above the navel, as is seen when the bladder is distended. On vaginal examination the cervix uteri was found softened and crowded against the symphysis, while a hard immovable hemispherical tumor could be felt in the pelvis posteriorly. This was supposed to be a hæmatocele, as the patient stated that she had menstruated regularly two weeks before. A large amount of turbid urine was removed by an elastic catheter. The physician soon satisfied himself that the tumor consisted of a retroflexed gravid uterus, and easily replaced it by putting the patient in the knee-elbow position. After two days the urine was passed at will. On the fourth day the patient was found in an excellent condition, but stated that after urinating she had forced from the genitals, with much pain, a ragged membrane, which had subsequently been withdrawn. This was the mucous membrane of the bladder. She soon recovered, and three months later gave birth to a healthy child. Two months after, she suffered from a catarrh of the bladder, connected with retroflexion of the uterus. This yielded to treatment. Schatz and Moldenhauer have published similar cases, from which, however, this is said to differ in the following particulars. (1.) The pregnancy had reached the sixth month, while in Moldenhauer's it had only reached the fourth. (2.) The pregnancy ran its normal course without expulsive efforts, while in the other case there was abortion, followed by death. (3.) The mucous membrane of the bladder was not gangrenous, as in the other cases. (4.) The retroflexion was only partial.—*Archiv f. Gynack.*, v. 1874.—*Schmidt's Jahrb.*, 1874.

TENOTOMY IN THE TREATMENT OF FRACTURE OF THE LOWER JAW.—A machinist came under the treatment of Estlander, having sustained a double fracture of the lower jaw from a heavy blow, the lines of fracture on either side passing through the mental foramen. The separated portion of bone was drawn strongly backwards and downwards, and could only be replaced by using considerable force, but it was found impossible to retain it in place, though many different kinds of apparatus were tried. To overcome the difficulty, Estlander divided the tendons of the genio-glossus, genio-hyoid and digastric muscles, after which there was no difficulty in replacing the fragment and keeping it in place. Neither the tongue nor hyoid bone were materially affected, and the patient made a good recovery.—*Nord. Med. Arkiv.*, 6, 1874.

ACTION OF MUSCARINE ON THE PUPIL AND ON ACCOMMODATION.—Among the effects that Schmiedeburg

and Koppe observed were caused by muscarine, the alkaloid principle of *agaricus muscarius*, were, at first, marked spasm of accommodation, and subsequently, after a prolonged action of the drug, a considerable myosis. The latter effect varied notably in different animals. It was very marked in cats, and very slight in rabbits.

Krenchel, in the *Hospitals-tidende*, for March, 1874, gives a sketch of a series of interesting experiments that he and Mulder made in Donders' laboratory. After dropping a solution of muscarine, varying in strength from one to thirty per cent., in the conjunctival sac of his own eyes and in those of several colleagues, the near and far points and the diameters of the pupils were measured with great accuracy. The result of these investigations showed that muscarine, like physostigmine, produces myosis and spasm of accommodation, but that they also present the following differences in their action. Muscarine always produces spasm of accommodation first, and in some persons this is its only effect; if myosis occurs subsequently it lasts from four to six times as long as the spasm of accommodation. The action of physostigmine on the accommodation begins with an approximation of the near point, in other words, there is an increased power and range of accommodation; a stronger action of physostigmine is necessary to produce spasm. The action of muscarine, on the contrary, commences in all cases with a spasm, and it is only after stronger doses that approximation of the near point occurs, though the latter effect is less marked than the spasm. The result is, therefore, in all cases a diminution of the range of accommodation. Hence the author considers that physostigmine is better suited to antagonize atropine than muscarine.

MODIFICATIONS IN THE OPERATION FOR RECTO-VAGINAL FISTULA.—At a recent meeting of the Société de Chirurgie, of Paris, M. Tillaux showed an instrument intended to facilitate the operation for recto-vaginal fistula. It is constructed on the principle of Desmarre's forceps for the enucleation of cysts from the eyelids, and consists of two blades, one in the form of a ring, the other solid. One blade is introduced into the rectum, the other into the vagina, and when approximated they limit the borders of the fistula, which can then be pared, according to M. Tillaux, without any loss of blood; and sutures may then be passed, as the solid blade is concave and furnished with a horn plate, which allows the passage of needles and sutures. M. Démarquay had made a series of operations for this disease and had failed. The cause of failure he attributed to the accumulation of the fæces, and also to the stretching of the parts during the act of defæcation, when the cicatrix gives way, either wholly or partially, and the fæces pass again into the vagina. There was also an anatomical condition of failure, the tension in the transverse direction of the lower wall of the vagina. He described the operation which he had tried with success, and divided it into two stages. The first stage consists in cutting through the posterior wall of the rectum as far as the coccyx, as in the operation for fistula in ano. This, in the first place, relaxes considerably the posterior wall of the vagina; and, secondly, it allows one to operate on the fistula, through the rectum, having it completely in view; thirdly, it allows the contents of the bowels to escape freely. The second stage of the operation comprehends several details; first, the edges of the fistula are very freely pared by oblique cuts, as in the operation for vesico-vaginal fistula by the American method; secondly, the edges having been freely pared and the flow of blood arrested, M. Démarquay inserts one

metallic suture by means of Blandin's curved needles, passing it through the posterior wall of the vagina; he unites the cut surfaces accurately by a number of points of suture, which are secured together in the vagina, as in vesico-vaginal fistula. This is easily done, owing to the relaxation of the parts, consequent on the deep incision of the sphincter ani. The contents of the rectum, on account of the division of the sphincter, remain but a short time in it, or if it be found necessary, their evacuation may be easily effected by a gentle laxative.

Injections of cold water are made daily into the vagina. He suggests that it is best to leave the sutures *in situ* for eight or ten days. The wound of the posterior wall of the anus cicatrizes, as in the operation for fistula in ano. M. Démarquay's patient, thus operated on, recovered. To those who may consider the preliminary operation proposed as serious, M. D. says that he has often performed it with the view of facilitating operations on the rectum, and that he had never met with any disagreeable consequences.—*The Medical Press and Circular*, December 23, 1874.

SCROFULOUS ULCERATION OF THE BLADDER RUNNING AN UNUSUAL COURSE.—At a meeting of the Clinical Society of London, held November 27, 1874, Mr. Edwin Humby read the notes of a case of the above disease. A little girl, aged 9, had suffered for some time from irritability of the bladder, accompanied by pain in micturition. The urine was ammoniacal, and contained some mucus, but no blood. Under the supposition that there might be a stone in the bladder, she was seen by Mr. Prescott Hewett, who diagnosed scrofulous ulceration of the bladder, and prescribed cod-liver oil and iron. Subsequently the child had some febrile symptoms, which were followed by the appearance of a swelling between the umbilicus and pubes. The swelling became red, tense, and eventually pointed, and appeared about to burst; instead, however, of doing so, a large quantity of pus was passed by the bowel, and the swelling for the most part subsided. From this time it varied much in size, in accordance with the amount of discharge from the bowel; occasionally it was tympanitic, being filled with flatus. Subsequently a small perforation took place in the swelling at the umbilicus, and through this a thin watery fluid oozed until the child's death. At the post-mortem examination the bladder was found to be very much thickened, with extensive ulceration of its mucous membrane, and patches of tubercular deposit between it and the muscular coat. In front of the bladder was a circumscribed cavity containing pus, and communicating with the bladder behind and with the perforation of the abdominal wall in front. At the back of the bladder was a second perforation leading into the rectum. The other organs were healthy. Mr. Hayward said that one means of diagnosis is the fact that in scrofulous disease the pain is worse before micturition, probably from stretching, and is relieved when the urine was passed.

Sounding should be avoided, at any rate, more than once. He had seen this followed in one case by severe hemorrhage. He had never seen a case proceed to abscess or ulceration into the bowel. Mr. Prescott Hewett related a case which had been under his care, and in which a pouch was formed in front of the rectum, obstructing the feces. This pouch was opened by the finger alone, and much pus discharged. Post-mortem examination some time afterwards verified the diagnosis of scrofulous disease.

He regarded Mr. Humby's case as peculiar, inasmuch as "the other organs were healthy." This was very unusual, the ureters, etc., were generally diseased, and,

if the patient recovered, he might die of phthisis. Recently he had seen scrofulous disease of the bladder and of the knee in one patient.—*British Medical Journal*, December 19, 1874.

HEADACHE FROM EYE-STRAIN.—It is well known that headache is a symptom of many intra-ocular disorders, but neither in the works on the eye, says Dr. S. Weir Mitchell, nor elsewhere, is it made plain that headache may be for years almost the sole symptom of grave disorders of accommodation or of defects in the orderly action of the external eye muscles. Dr. Mitchell has often seen the sequence, and in cases of chronic headache, insists upon a careful examination of the eye, and has often been rewarded by finding the pain fade away when the optical effect has been duly corrected. The strain caused by the various forms of astigmatism often causes headache; but a light insufficiency of some one of the extra-ocular ball muscles is far more likely to give rise to it. In all of them the headache comes by degrees, and is at first found only following long use of the eyes. By and by, almost any use of the eye causes pain. The over-effort made to correct or accommodate, and converge or diverge the eyes, at first causes pain only on such effort; but at last the teased brain gets to aching when the patient is not trying the eyes, when he is thinking or doing a little mental arithmetic, or the like. Facts like these have often made physicians overlook the eye trouble as the true parent of the pain. When once the intra-ocular or oculo-motor trouble has been relieved, it seems natural to suppose that the headache would at once disappear, but, in fact, it fades away but slowly, and sudden entire relief is rare.—*Philad. Med. and Surg. Rep.*

CONTAMINATED DRINKING-WATER AND TYPHOID FEVER.—Dr. Haegler, of Basle, gives the details of an outbreak of typhoid fever in the village of Lausen, near Basle, where the ordinary conditions that have been said to govern the disease, such as the character of the subsoil and subsoil water, were extremely unfavorable for the development of the disease, and where in fact for a long time there had been no typhoid. In August fifty-seven cases occurred within a space of nine days, and in all the houses of the village except six, while these six drew their water-supply from a source entirely different from the others. On investigation it was learned that two months previously there had been cases of typhoid in a farm-house not far from the village, and that the dejections of the patients had been thrown into a little stream running through the yard or into a ditch communicating with it; this stream joined the larger one that supplied the village. Other excrementitious matter had also been thrown upon dung-heaps, from which a drain led to the same stream. Dr. Haegler concluded from these facts:—1. That the epidemic of typhoid fever in this instance was the result of drinking-water contaminated with the dejections of typhoid patients. 2. He believes that typhoid fever depends upon a specific poison obtained from typhoid patients. Other putrid matter and decomposing organic substances, and, at any rate, the filth of privies and dung-heaps, with which the typhoid dejections may be mingled, cannot produce the disease, since this instance shows that the drinking-water of the town had been fouled by these substances for years without producing any bad result. 3. The ordinary filtration of contaminated water by its passage through the ground, will not disinfect the water or furnish any protection against the action of the typhoid poison.—*Deutsch. Archiv f. klin. Med.*, xi. 1874. *Rundschau*, Nov. 1874.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 6, 1875.

THE TEACHING OF SPECIALTIES IN THE MEDICAL SCHOOLS.

IN a recent issue of this Journal we expressed the opinion that our system of Medical education would be improved by establishing special chairs in the general courses of lectures at Medical Colleges, premising, however, that the instruction in all these special departments should be given with the sole idea of their utility to the general practitioner. Allusion was also made to the advances which have already been brought about in this direction. In the larger Schools of Medicine, physicians specially learned and skilled in diseases of the eye, the ear, the skin, the chest, the nervous system, in syphilis and in gynæcology, now impart instruction during some portion of the curriculum. Surgery, in its higher branches, has been so long recognized as a necessary specialty that it is hardly looked upon as a specialty at all. In some of the smaller schools, however, specialties are not yet taught: and even in the larger schools they are often so subordinated to what is styled the general practice of medicine, that many of the students are in danger of neglecting to acquaint themselves with elementary principles and methods of treatment which ought to be understood by every general practitioner.

In fact there are two dangers, the one to which reference has already been made, that students after hearing a course of lectures on some branch of medicine that has been classed as a specialty, may imagine themselves competent to treat the most difficult cases that come under their care; and the opposite danger, that they will neglect instruction in specialties altogether, because they are made to appear as though they were divorced from general practice, and because they are sometimes taught with too much minuteness, as though each student were being educated to rank as an expert in the specialty.

In order to teach a subject well the teacher should have a vast fund of experience and information as a

basis on which to found the elementary principles he teaches. This is the reason why a specialist is more competent to instruct on the theory and practice of his specialty than other physicians are. But he should remember that his specialty is, after all, only a part of general practice; and that the extent and prolixity of his teachings should not be such as to engross too much of the student's time, nor should he attempt to teach those abstruse points and difficult applications that can be learned only by prolonged, patient and special study. Such a course may serve to advertise the learning and skill of the teacher, but can be of little service to the student who is still engaged in studying the elementary principles of his future profession. If the well-instructed general practitioner desires to study a specialty, let him take a post graduate and special course, and let that course be as thorough as may be desired. The medical student, however, needs to learn such doctrines and such practices only as he can thoroughly master, and as will be of most service to his future patients, taking into due consideration the frequency and acute character of the diseases in question: and he should learn these doctrines and practices from those who understand them best. In regard to the more abstruse doctrines and difficult operations, a concise and general statement, including the methods of diagnosis, will be all that he requires.

But while many specialties in medicine have obtained a recognition in at least some of the schools, there is one important specialty, the teaching of which has been for the most part neglected. The pathology and treatment of diseases affecting the mind have thus far received little attention in American Schools of Medicine. It is true that a few lectures on the subject have been given, but it is doubtful if in any case these lectures have been sufficiently elementary and practical in character, and sufficiently extended to be of much service as a guide to general practitioners in the management of those acute cases of insanity they may be called upon to treat. There seems to be a general impression that insanity is a subject entirely beyond the scope of ordinary physicians—a subject so abstruse that it can be understood only by those who have made it a special study for a long period of time. This, certainly, is a mistake. As in other specialties so in this, there are difficult cases, the diagnosis and treatment of which require special skill and experience; but there are also many and very important cases in the diagnosis of which there is little difficulty, and in the treatment of which students of medicine may easily be instructed.

In some of the European schools the teaching in insanity has been extended and thorough. It is not the fault of the superintendents of American institutions for the insane that the teaching in American schools of medicine has not been equally extended and thorough. As an evidence of this we quote a series of resolutions unanimously adopted at their

meeting in Toronto, in 1871. Dr. Kirkbride, Dr. Walker and Dr. Everts had been appointed at a previous meeting as a committee on the subject of didactic and clinical instruction in insanity. The following are the resolutions reported by Dr. Kirkbride, the chairman of the committee, and unanimously adopted by the association, viz.:

Resolved, That in view of the frequency of mental disorders among all classes and descriptions of people, and in recognition of the fact that the first care of nearly all these cases necessarily devolves upon physicians engaged in general practice, and this at a period when sound views of the disease and judicious modes of treatment are specially important, it is the unanimous opinion of this association that in every school conferring medical degrees, there should be delivered, by competent professors, a complete course of lectures on insanity and on medical jurisprudence, as connected with disorders of the mind.

Resolved, That these course of lectures should be delivered before all the students attending these schools; and that no one should be allowed to graduate without as thorough an examination on these subjects as on the other branches taught in the schools.

Resolved, That in connection with these lectures, whenever practicable, there should be clinical instruction, so arranged as to be in no way detrimental to the patients, while giving the student practical illustrations of the different forms of insanity and the effects of treatment."

The following resolution was then adopted, viz.:

Resolved, That a copy of these resolutions be sent by the Secretary to the American Medical Association, the Dominion Association and Ontario Association of Canada, to each State Medical Society, and each Medical College in the United States and British Provinces."

During the discussion of the resolutions Dr. Kirkbride made the following remarks: "In reference to this matter of didactic and clinical instruction in cases of insanity, I may say that it is not a new one. Both were given in Philadelphia long since, as far back as the time of the distinguished Dr. Rush. . . . Lectures on insanity clearly ought to be a part of the regular winter course, and students should be as carefully examined on this subject as on any other branch of medicine, before commencing the practice of their profession."

At a future time we will lay before our readers some important considerations in support of the above resolutions.

SPECIAL INVESTIGATION OF DIPHTHERIA BY THE HEALTH BOARD.

THERE seems to be no doubt, from the numerous facts now in our possession, that a very large percentage of the mortality in our cities and towns, as well as in

the country at large, may be the result of neglecting sound sanitary rules. As an instance, we are told that where towns have long been subject to severe epidemics, these have abated very remarkably after the introductions of proper drainage and a good water-supply system. There is a class of epidemics, however, in which it is not very clear that these same rules operate. This is true of diphtheria, for though, as is well known, many believe it to be miasmatic, in the sense that it originates from some source without the body, there are others who as strongly believe that it is contagious, *i.e.*, propagated by direct contact with the diphtheritic matter of the sick person. This question is certainly an intricate one, and either view presents difficulties, but it should be our aim to try and solve it, for a knowledge of these facts are of the very first importance to any community where the disease prevails. If we do not understand its nature and origin, how can we devise means for its prevention or intelligent treatment? We are glad to know that the Board of Health has authorized the proper investigation of these points. It appears as if this step on the part of the Board is the only one likely to elicit the proper information on the subject.

It is quite evident that our medical bodies, such as our medical colleges and societies, whether city, state or national, are not in a position to gather the data that is necessary. They neither possess the requisite authority for getting this information, nor have they the funds for carrying out a systematic and extended investigation, though doubtless no class of the community is more earnest in its desires to stamp out a deadly malady. While as yet we have no general Sanitary Bureau in this country, and no thoroughly organized sanitary system, our dependence must be placed upon our local boards which, fortunately for us, have shown frequent proofs of their ability to contend successfully with disease.

It will be well for other local boards to take example by New York, and authorize a systematic examination of the prevailing diseases of their locality. It is only by the collection of such facts that we shall be able to lay the basis of sound sanitary laws.

ALUMNI ASSOCIATIONS.

IN several of our large cities the Alumni Associations are making very active endeavors to advance the cause of medical education in our Colleges. Already they have excited an influence which is beginning to be felt in every direction. New York has three such organizations which, although in good working condition, require more funds to accomplish their avowed object. If the profession keep this latter fact in mind they will obviate the necessity of being surprised at the forthcoming annual appeals.

CHICAGO.—There are six hundred and fifty doctors in Chicago.

Reviews and Notices of Books.

CLINICAL LECTURES UPON VARIOUS IMPORTANT DISEASES. By NATHAN S. DAVIS, M. D., Professor of Principles and Practice of Medicine and Clinical Medicine in Chicago Medical College. Second edition, edited by FRANK H. DAVIS, M.D. Published by Henry C. Lea, Philadelphia. 1874.

This little book contains about 283 pages of reading matter, made up of clinical lectures given at the bedside of patients in the wards of Mercy Hospital, Chicago. The subjects considered are—continued fever, periodical fever, rheumatic fever, scarlatina and rubella, respiratory affections, diseases of the alimentary tract, cardiac disease, neuralgia, and various nervous affections, kidney diseases, etc., etc. The book presents a very satisfactory external appearance, but we are surprised that it ever reached a second edition. From the well-known reputation of the author of these lectures the medical reader had a right to expect a more correct presentation of these subjects than is here given. We are, however, sufficiently charitable to believe that the work has never undergone thorough revision by the author, but has been left to an editor who feels himself compelled to believe that whatever a man of note says must be accepted and reported just as he said it.

As the book now stands, it contains more inexcusable blunders than we have met in a book of equal size in a long time. The therapeutics of the book are amusing in most instances, and are such as might well lead to the conclusion that the prescriber has almost unlimited faith in the efficacy of remedies. If we knew that we were to have continued fever, phthisis (which the author regards as due to tubercles), pneumonia, etc., etc., and were to be treated according to the plans laid down in this book, we should be sorry that we had exposed ourselves to these diseases.

With regard to the grammar, we cannot help directing attention to one sentence as being worthy of special consideration. On p. 16 we have: "Such practice not merely prostrates the patient, but it directly increases the irritability of the mucous membranes with the aggregated glands of Peyer, which so generally constitute an important pathological condition in all varieties of continued fever." There is a pathological item in this sentence also which is somewhat novel. The distinctions between typhus and typhoid fevers given in these clinical reports are such only as lead to the conclusion that the two diseases are identical, which we find hard to believe.

On p. 182 a *regurgitant* murmur is made to appear at the apex of the heart, synchronous with *diastole*, and that in absence of murmur at the base of the heart. This is an item in physical diagnosis of which we have not heretofore heard. On p. 277 we find the following sentences, which may be their own interpreters: "Most recent writers describe three varieties of pneumonia—the croupous, the catarrhal, and the interstitial or chronic form. The second variety differs from the first chiefly in the fact that the inflammation involves the smaller bronchial tubes and air-vesicles, as well as the structure of the lung." Upon the whole, the book does not reflect credit upon the editor, author, nor profession generally; and we sincerely hope, contrary to the expressed wish of the editor in his preface, that it may never be read by any medical student or young practitioner.

A GUIDE TO THE PRACTICAL EXAMINATION OF URINE. By JAMES TYSON, M.D. Pp. 182. Lindsay & Blakiston. Philadelphia.

EXAMINATION OF THE URINE. By GEORGE B. FOWLER, M.D. Pp. 80. D. Appleton & Co., New York.

The appearance of two more little volumes upon the subject of Urinary Examination would imply that, to book-makers at least, the subject is one deserving of more attention than has hitherto been allotted to it. Until quite recently we have been obliged to depend entirely upon foreign literature for information upon this subject. The publication, therefore, of an American book should secure for it the consideration and encouragement which its merits demand.

Dr. Tyson's book contains the information necessary to enable the student and practitioner to make a thorough qualitative and quantitative analysis, and microscopical examination of the more important ingredients of the urine; and the information conveyed is reliable, showing the author to be practically acquainted with the subject of which he treats. Due attention is paid to the volumetric methods, and the precautions necessary in their employment are noted. The *approximative* methods, however, to which the author calls attention in his preface, are altogether too *inapproximative* to be of any value. For instance: "From normal urine containing half to one per cent. of chlorides there are precipitated by a single drop of a solution of nitrate of silver, 1 part to 8, in cheesy lumps which do not further subdivide themselves. If, however, the *colorides* are *diminished* to one-tenth per cent. or less, the addition of a single drop of the silver solution no longer produces the white cheesy lumps, but a simple cloudiness," etc. A method which does not furnish a reliable indication between .5 per cent. and .1 per cent. is hardly to be commended. With this exception and the fact that the book lacks a table of contents, Dr. Tyson's work is one which does credit to its author.

Dr. Fowler's book unfortunately belongs to a different category. Of its eighty pages we have turned down the corners of more than a dozen which contain either distinct errors or careless and inexact statements. Among the errors we find the formula for Fehling's solution, p. 60, incorrectly given. The author has apparently copied the *English* formula without attention to the fact that English and American fluid ounces are not identical. Among the inexact statements is the following: "Under the blowpipe it is consumed, being of organic origin, and a black ash remains." If it is *consumed* how can a *black* ash or anything else remain? The book bears evidence of careless proof-reading in the frequent occurrence of orthographic peculiarities, such as, diabetes *insipitus*, *miletus*, etc.

TRANSACTIONS OF THE PATHOLOGICAL SOCIETY OF PHILADELPHIA. Volume Fourth. Containing Reports of the Proceedings for the Years 1871, '72, '73. Edited by JAMES TYSON, M.D., Recorder of the Society, etc., Philadelphia. Printed for the Society by J. B. Lippincott & Co. 1874.

In this work a careful attempt has been made to arrange the matter presented, and the effort has been attended with a good degree of success. The history of the specimens presented has been arranged under the following heads: (1) Those belonging to the osseous system; (2) to the digestive apparatus; (3) to the vascular system; (4) to the respiratory system; (5) to the genito-urinary apparatus; (6) to the nervous system; (7) to the organs of special sense; (8) tumors not otherwise classifiable; (9) miscellaneous specimens; (10) specimens from the lower animals.

In several instances specimens have been illustrated by wood-cuts, which materially adds to the interest of the volume. In general, the book presents a very acceptable appearance, and furnishes the profession with reports of cases which are of undoubted value. We predict that if coming volumes, which have been promised, present evidences of the same care in their arrangement and appearance, they will be quite acceptable to the profession.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 13, 1875.

DR. H. KNAPP, PRESIDENT, in the Chair.

ENCEPHALITIS—ABSCESS IN BRAIN—PARALYSIS.

DR. LEWIS SMITH presented a specimen with the following history:

Maggie, aged 2 years 8 months, was admitted into the Catholic Foundling Asylum about the 1st of September, 1874. She seemed to be in good health and was plump and well-developed, and her mother stated that she had had no serious sickness. After her admission she continued well, having the usual appetite, amusing herself through the day, and presenting no symptoms to attract attention till December 6th. On the evening of December 5th she ate her supper as usual, and was placed in her crib, *apparently in perfect health*. At 3. A. M. the sister, who was in charge of the ward, found her in severe general eclampsia. Immediately, in addition to the usual local treatment, she administered 5 grains of bromide of potassium, and this was repeated at intervals till six or seven doses were administered. Nevertheless, the spasmodic movements continued, with more or less violence till 1½ P. M., and in the muscles of the neck somewhat longer.

On my arrival at the Asylum at about 6 P. M. I found her lying quietly, rather stupid, but easily aroused. Her vision was evidently good; and she was conscious; the pupils responded to light, and the direction of the eyes was normal; pulse 104, no cough, and respiration natural; temperature, as ascertained by the thermometer in the axilla, also normal. There was no apparent paralysis of the muscles of the face, but the right arm and leg were paralyzed, though the paralysis was not complete. The great toe flexed on tickling the sole of the foot, but the foot itself had little or no motion, and on my attempting to flex the leg, which was extended, some rigidity of the muscles was observed. At times the patient produced slight movement of the thigh upon the trunk. The muscles of the right upper extremity were more flaccid than those of the leg, and below the elbow motion seemed to be totally lost, while a little movement remained of the arm on the trunk. I think that during the two or three days succeeding the convulsions sensation in the right limbs was not entirely lost, though greatly enfeebled. Subsequently paralysis in the right limbs, both of the nerves of sensation and motion, was nearly or quite total, and continued so to death. Nevertheless, tickling the sole of the foot caused some movement of the great toe. On the left side sensation and motion were perfect.

The record of December 9th runs: Has vomiting to-day for the first time; apparently sees well, and appearance of the eyes normal, has no retraction of head or rigidity of muscles of neck, or along the spine; pulse 96, temperature in the axilla normal;

lies quiet and with eyes shut; is stupid, but not particularly fretful, when aroused; the bowels move regularly.

December 11th, continues to vomit at intervals; pulse 68. Dec. 16th, pulse 80, temperature 100, vomited once yesterday, none to-day; lies in a constant doze; takes bromide of potassium gr. iv. three times daily. Dec. 18th, moans at times, as if in pain; pulse 180, temperature 100, takes the bromide gr. iv. every four hours.

Dec. 19th, pulse 180, temperature 103; there is convergent strabismus, and the eyes have a wild, almost insane look, but she sees, grasping hurriedly a percussion hammer presented towards her; paralysis of nerves of motion and sensation in the right extremities nearly complete, slight movement still being produced in the great toe by titillation; the vomiting has ceased; tongue covered with a thick fur; movements of the bowels pretty regular; has a slight cough, such as is common in cerebral disease.

Dec. 22nd, lies quietly on her side in perpetual slumber, with eyes constantly shut; pulse 118, temperature 101½; the bowels still move nearly normally; the pupils, exposed to the light, are seen to oscillate, but are constantly more dilated than in health; the urine passes freely; has at intervals circumscribed flushing of the features; a rash like lichen over abdomen and chest, possibly due to the large quantity of bromide of potassium administered. 24th, pulse intermittent; pupils dilated.

Dec. 25th, died in profound stupor to-day, having lived nineteen days from the commencement of the malady.

Autopsy.—About thirty hours after death, weather cool. On removing the calvarium and dura mater, which presented no unusual appearance, the vessels of the pia mater were found rather more injected than usual, but not more so than we sometimes observe in those who die of diseases which do not involve the brain. The cerebro-spinal fluid was scanty, and the surface of the brain rather dry. The vertex of the left hemisphere was unusually prominent, rising perhaps half an inch higher than that on the opposite side. At the highest point, which was about one and a half inches from the median line, was a circular yellowish spot upon the surface of the brain about one and a half inches in diameter. Pressure upon this spot, made lightly, so as not to produce rupture, communicated the sensation of a large cavity underneath filled with liquid, and approaching to within two or three lines of the surface. There was no adhesion or exudation at that point, and the surface of the brain appeared entirely normal, except a little cloudiness of the pia mater over a space which could be covered by a five cent piece, a little posterior to the optic commissure. The incised surface of the brain at a distance from the abscess showed no increase of vascularity. The right hemisphere appeared in every way normal, except that its lateral ventricle was filled with pus, but not distended.

On the left side, occupying the centre of the hemisphere, was an abscess as large as the fist of a child of two years, extending from within two or three lines of the vertex, where its site corresponded with the yellow spot on the surface of the brain, to the roof of the lateral ventricle. Through this roof the abscess had burst, filling and distending the ventricle with pus, and thence making its way into the lateral ventricle of the opposite hemisphere. The whole amount of pus contained in the abscess and the two ventricles was perhaps two ounces. The walls of the left lateral ventricle were much softened, the upper part of the corpus striatum and thalamus opticus being nearly disfluent;

the walls of the right lateral ventricle were slightly softened, but to less depth. The parieties of the abscess, which extended from the roof of the ventricle to the vertex, as already stated, were indurated to the depth of one and a half lines in consequence of proliferation of the connective-tissue, except at the base of the abscess, which corresponded with the roof of the ventricle where softening had occurred. The spinal cord, so far as it could be examined from the cranial cavity, had the usual vascularity, but was slightly softened. The diseased portion of the brain was sent to Dr. Heitzmann, immediately after its removal, who will state the microscopic appearances.

The cause of the encephalitis from which the abscess resulted was obscure. This inflammation, so far as can be ascertained, was idiopathic, which is known to be a rare disease. There was no history of otitis, which is one of the most frequent causes of cerebral abscess, nor of heart disease, so as to produce embolism. It seems probable, since there was no fever till about the fourth day after the convulsions, that an abscess had primarily occurred in the hemisphere between the roof of the ventricle and the vertex, possibly weeks previously. The bursting of this into the lateral ventricle, and the constitutional disturbance, inflammation and softening to which this would inevitably give rise afford sufficient explanation of the history of the case, after the commencement of the convulsions.

It is quite customary to refer the paralysis of young children to disease of the spinal cord, and if no opportunity occurs of discovering the true lesion by an autopsy, it is usually taken for granted that the malady has a spinal origin. This case, however, shows that sudden and incurable paralysis sometimes occurs in very young children from brain disease, as it does in the adult. Indeed, as regards the laceration and destruction of brain substance, the condition was very similar to that in severe apoplexy of the adult, which so often gives rise to hemiplegia. It is well known that in right hemiplegia of the adult the loss of speech is common. This child also lay quiet and speechless, but no attempt was made to discover whether or not speech was possible, as no attention was given to this feature of the case.

DR. HEITZMANN made the following report of the microscopic appearances:

The left hemisphere of the brain brought to me by Dr. Lewis Smith, about half an hour after having been removed from the body of the child, was very soft, more so than we find it in the healthy condition of the same in children. The internal membranes of the brain were in a high degree hyperæmic, and a little dim, especially on the basis. On the lateral surface of the parietal lobe there appeared a yellow patch, of the diameter of about $1\frac{1}{2}$ inches, transparent through the arachnoidea and pia mater. After hardening the specimen in a solution of bichromate of potash, I removed the upper portion of the hemisphere, when an abscess presented itself of the size of about a child's fist, located in the white substance of the hemisphere, divided into two parts by a segment, surrounded by a wall of harder consistence than the adjacent tissue. The latter was softened by œdema.

By applying some pressure on the wall of the abscess, a large quantity of pus issued forth from the open lateral ventricle, so that a communication between the two cavities was evident. The cerebellum and the medulla spinalis, of which I also received a portion for examination, presented only a softer consistence than in the normal state.

The microscopic examination of the freshly-removed pus was very interesting. In the same were suspended

a number of granular and rodlike corpuscles, which moved freely in the liquid, the so-called micrococci and bacteria. Besides these, there were dispersed plaques of greatly varying sizes, composed of a number of closely situated dark granules. Most of these plaques were several times larger than ganglion-globules. In some of them there were observed some indistinct nuclei.

The largest portion of the pus consisted, of course, of pus-corpuscles, with one, two or more nuclei; some of them were also without nuclei. These corpuscles being examined with a high power, showed very distinctly the structure of the protoplasm similar to that of corpuscles of the blood of men which I have described two years ago. The only difference between the two is, that in the pus-corpuscles the living matter appears in the form of granules of a larger size than those of the blood-corpuscles. Moreover, in the pus there were corpuscles corresponding in their shape and size to those of ganglion globules, with different transitions of their protoplasm into pus-corpuscles, appearances which (as far as I am aware) have only been described by Meynert of Vienna and Robinson of this city. Similar transitions were found in the layer of nuclei of the gray matter of the brain, in the immediate vicinity of the abscess.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Meeting, January 22, 1875.

DR. PEASLEE, PRESIDENT, in the Chair.

The paper for the evening was read by Dr. J. C. Peters, and consisted of a historical sketch of the origin and progress of the Medical Library and Journal Association of New York. The first meeting preparatory to the organization of this Society was held at the house of Dr. Isaac E. Taylor, in August, 1864. All the earliest meetings were held at the same place. The first President of the Association was Dr. Edward Delafield, and many meetings were held at his house. The original design was to establish a medical reading-room, where all the most important medical journals could be found, and also to have reunions in imitation of those held at the Royal College of Surgeons in London. Furthermore, it was designed to make the library a nucleus for a medical club-room. In some respects it had been necessary to depart from this original design.

The first rooms occupied by the Association were at the corner of Fifth Avenue and 22d Street, and the rent paid was \$600 a year. The janitor was a small boy, who, besides being dirty and shiftless, seemed to have a supreme delight in being absent when his services were most needed. The next rooms occupied were at the corner of Broadway and 18th Street. The services of a janitor were there dispensed with. The next room occupied was a dark, hot, badly ventilated back-room, upon Madison Avenue. There the Association had first a female janitor, and then a male, and the salutations were the crowing of a cock and the bark of a dog. But at this place the rooms were open regularly, and the first regular start at least was given to the Association.

The rooms that are at present occupied by the Association, are comparatively pleasant, and are already overflowing both with members and books. Notwithstanding this present comparatively easy and prosperous state of affairs, the annual income of the Society is now, at the end of ten years, less than \$3,000. Some of the members do not pay at all, and

there are very many who are exceedingly dilatory in this respect. These remarks were made in behalf of all our medical societies. In general, the most prompt to pay are those who are least able, and those who are best able to pay are most dilatory, and, in some instances, have refused to pay upon the least excusable ground. The executive committee have resolved to post the names of members neglecting to pay their dues, which will save the collector and treasurer very much labor, and it is believed, will be beneficial to the Association.

About ninety-four journals are now taken, and the library contains about 3,500 volumes.

In the autumn of 1864, the officers of the Association were for the first time recommended by a Committee on Nomination.

Dr. Edward Delafield was nominated and elected President.

The following gentlemen have since that time served as Presidents of the Association:

Dr. Edward Delafield, 1865-6; Dr. Gurdon Buck, 1867-8; Dr. Isaac E. Taylor, 1869-70; Dr. Isaac Hubbard, 1871; Dr. Alfred Underhill, 1872; Dr. J. C. Peters, 1873-4; Dr. Peaslee, 1875.

The rooms are open the greater part of the day and evening, where subscribers may go and read and study at their leisure. The library consists of a respectable collection of medical books, and among these are the medical libraries of the late Drs. Batchelder, Elliot, and Foster. The stock of medical journals is steadily increasing.

Dr. HUBBARD remarked that the success of all associations depends, in a very great degree, upon the punctuality of payment of dues among the members. It was this that kept this Association alive amid its darkest hours. Every member should feel himself under obligation to pay his annual dues to any such Association just as he pays any other indebtedness incurred in business relations.

Discussion was continued by Drs. Burrall, Emerson, Sell, Post, and Peaslee.

Dr. PEASLEE fully endorsed posting every member's name who was dilatory in the payment of his dues. He offered the suggestion that inasmuch as the original idea of the Association had been somewhat departed from, perhaps it would be well to concentrate their energies in making it a *Journal Association* alone, and relax them somewhat in the direction of establishing a library in the same connection. This was suggested in view of the fact that a sister society had already taken steps towards founding a library, where in one year they would collect double as many books as the Association now had. Would not their energies, concentrated in the direction of making the Association a *Journal Association* and not a *Library and Journal Association*, be more profitable than an attempt to carry out the two in conjunction?

After extending the customary vote of thanks to the author of the paper, the Association adjourned.

OCCUPATION AND LONGEVITY.—The opinions of country doctors all over the State have, during the past year, been obtained by the Massachusetts Board of Health, with a view to determine the effect of occupation on longevity. It appears that a table collated for twenty-eight years shows the average age of farmers at death to be 65.13 years—figures far in advance of any other callings, and greatly exceeding the lifetime of active mechanics, not in shops, who, averaging 52.62 years, appear next on the list. The opinions of the physicians consulted also show that the farmer's chances of long life are somewhat greater than those of any other class.

Correspondence.

IS IT ALL TRANCE AND TRICKERY?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The paper of Dr. Geo. M. Beard, recently read before the County Medical Society, and published, in abstract, in the last number of your journal, deals with a subject of more than ordinary importance, a subject of so much interest that for the last century scientific men of all civilized countries have labored in vain for a perfect solution of the physiology of the several mental states that Dr. Beard has at last made so clear.

I think, however, this gentleman dismisses the subject too lightly when he pronounces the various states of unconscious cerebration as mere "trickery and trance." Carpenter and other distinguished physiologists take an entirely different view of these questions, and too many well-known and well-authenticated instances of psychic phenomena are on record to dismiss this subject with Dr. Beard's verdict. The detection of all the humbug and deceptions of so-called spiritualism, and disclosures of clap-trap have always followed too soon for any right-minded individual who thinks and investigates for himself to be deluded any longer. There are conditions, however, that must attract the attention of unbiassed observers. Setting aside animal magnetism, which is a term only used by charlatans, and "psychic force" which has been proved by competent observers not to exist, we still have to search for and study a condition—I may call it a force which is neither "trickery" nor "trance." No one can deny that certain individuals may impress others, that the weak yield to the strong, that certain individuals act in direct opposition to their instincts and knowledge of right and wrong when influenced by others. The word "trance" is too vague, too broad to cover all the delicate phenomena of the several interesting states commonly denominated mesmerism, clairvoyance and "mind-reading." Expectant attention and unconscious muscular action explain some of the phenomena, but even after divesting them of their quackish and catch-penny character, there is a great deal left. The report of the French Academy is a scientific example for committees in general to follow.

There is no doubt but that the man Brown and others have degraded the faculty developed in them, but I have myself witnessed and tested too many of these phenomena to slur them over. We should "rule out" superstition and trickery, but even then we have to look the matter squarely in the face.

The popular examples of the transmission of a yawn—both persons being unconscious of the action; for the fact that one person, by simply imitating the motion of the jaws with his hands, may induce it in another, are exhibitions of this unknown influence.

To study the transmission of voluntary impressions, would it not be well to answer the following queries?

1. Can an impulse or influence be transmitted from A to B without cognizance of either, but with response from B?

2. Can a volitional mandate be transmitted from A to B, with knowledge of A, and ignorance and response of B?

3. Can a volitional mandate be transmitted from A to B, the character of which is not known to B, but he alone knowing that there is an action to be performed?

Certainly these phenomena have not been clearly accounted for. Even Dr. Beard himself was unsuccessful.

ful in exposing them at a late meeting of the Society of Electrology and Neurology, and many others are unable to exert this power, in opposition to his statement that *all* may be so influenced—of course the claims of those pretenders who assert almost that they can see through the bones of the cranium, should be received *eum grano salis*—but there are many truthful and honest people who possess a faculty that is astonishing in the extreme.

Mr. Beard, and Dr. Carpenter, of England, have really written upon these subjects in a scientific and unprejudiced manner, and after reading their productions, all will, I am sure, attach much importance to the communication of mental impressions, and the productions in consequence of certain involuntary and unconscious muscular movements.

All of these things are not "trickery," and therefore they should not be considered as such without further study.

ALLAN McLANE HAMILTON.

117 EAST 26TH ST., N. Y., Jan. 23, 1875.

New Instrument.

AN IMPROVED SPECULUM.

PROFESSOR DANIEL T. NELSON, M.D., of Chicago, describes, in a recent number of *The Chicago Medical Examiner*, a new uterine speculum. It may in reality be called a modification of Nott's instrument, but differing from it in having the lower blade longer and of better shape to receive the neck of the uterus, and in having handles for elevating and holding the upper blades.

The measurements of the instrument are as follows: Lower blade, $4\frac{1}{2}$ inches, extending beyond upper blades $\frac{3}{8}$ of an inch; length of instrument, including handles, $7\frac{1}{2}$ inches. The upper blades are made shorter than the lower, to correspond with the anatomy of the parts.

To introduce the instrument: The patient reclines on the back upon the gynecological chair, with the hip near the edge of the chair. Having ascertained the position of the os uteri, grasp the speculum with the right hand, with the forefinger resting upon and projecting beyond the lower blade, and hold the handles vertical. Then carefully introduce the forefinger into the external organs and follow it with the instrument. When the instrument has passed beyond the external organs, it should be rotated so that the handles shall lay horizontally; then, pushing the lower blade along the posterior wall of the vagina, it will pass under the posterior labium of the os. Then compressing and bearing downwards and backwards upon the handles, the anterior vaginal wall will be raised and the os exposed, when the handles can be fastened by the thumb-screw. The instrument is self-retaining when sufficiently expanded.

If the os is not at first exposed, the instrument, partially expanded, may be withdrawn a little so as to allow the lower blade to pass under the os; or the os may be raised by the forefinger inserted through the expanded instrument, by raising the anterior wall of the vagina, there being ample room for the forefinger to pass between the expanded upper blades. Or the os may be raised into the field of the instrument by a Simpson's sound, or like instrument, used as a lever. When the os is exposed, the uterus may be held in the field by a tenaculum, which can be fastened to a hook on the right upper blade.

Dr. Nelson claims the following advantages for this instrument:—

1. Its length is such as to expose the uterus *in situ* by bringing it *nearer* the external organs, rather than pressing it deeper into the pelvis, as do the longer instruments.

2. It also gives a *better light*, which is often of great importance, especially when the physician is obliged to visit the patient at her home.

3. The instrument is so short, and the upper blades expand in such a manner as to readily allow of the rectifying of any malpositions of the uterus through the expanded instrument, which is impossible in all the long instruments.

4. A large portion of the *vaginal walls* are exposed for examination and treatment, if needed, and by rotating the instrument the whole may be exposed.

5. While the blades are short they are capable of expanding the vaginal walls more than any of the short instruments, and, indeed, more than most of the long ones.

6. The urethra and meatus are not pressed by the instrument, but lie between the upper blades, where they may be readily examined and treated if necessary.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from January 24th to January 30th, 1875.

BAILY, J. C., Surgeon.—Granted leave of absence for one month, provided he furnishes a suitable substitute during his absence. S. O. 11, Dept. of the South, January 27, 1875.

BACHE, DALLAS, Surgeon.—Temporarily assigned to duty at Baltimore, Md., Attending Surgeon and Examiner of Recruits. S. O. 16, A. G. O., January 26, 1875.

KNICKERBOCKER, B., Assistant Surgeon.—Temporarily assigned to duty at Fort Vancouver, until the season will admit his joining his proper station, Fort Colville, W. T. S. O. 5, Dept. of the Columbia, January 11, 1875.

WILSON, A. D., Assistant Surgeon.—Assigned to duty as Post Surgeon at Camp McDowell, A. T. S. O. 2, Dept. of Arizona, January 7, 1875.

JACKSON, D., Assistant Surgeon.—Assigned to temporary duty at Fort Concho, Tex. S. O. 10, Dept. of Texas, January 18, 1875.

The Medical Examining Board, in session in San Francisco, Cal., is dissolved, and the members thereof will rejoin their proper stations. S. O. 17, A. G. O., January 28, 1875.

MEDICAL ASSOCIATION OF THE EASTERN DISTRICT, BROOKLYN, N. Y.—At the annual meeting of the Medical Association of the Eastern District of Brooklyn, held January 21st, 1875, the following officers were elected:—President, J. A. Jenkins, M.D.; Vice-President, W. G. Russell, M.D.; Secretary, G. P. Griffing, M.D.; Treasurer, W. P. Morrissey, M.D.; Librarian, J. H. La Roe, M.D.; Delegate to American Medical Association, W. F. Sanford, M.D.

"EAST RIVER MEDICAL ASSOCIATION" OF THE CITY OF NEW YORK.—Officers for the year 1875:—President, Robert A. Barry; Vice-Presidents, Alex. W. Stein, James W. Bowden; Secretary, William J. Purcell; Treasurer, Verranus Morse.

Medical Items and News.

CHOLERA ON BOARD SHIP.—The ship *Forfarshire*, which left Calcutta for Demerara on the 18th of August last, with one hundred and fifty coolies on board, had an outbreak of cholera when two days out. Within eight days forty cases occurred among the coolies, and in five days no fewer than thirty deaths took place. To add to the distress of the situation, measles appeared among the children, five of whom died from this disease, in addition to twenty-two from cholera. The death-list on the passage amounted to fifty-two souls. There is no information as to the presence of a medical officer on board.

HARVARD COLLEGE.—The corporation has erected a small pavilion hospital in an isolated position, with every convenience for taking care of the sick, thus enabling the college to protect itself in the future against epidemics, with which on one or two occasions it has been threatened.

The pecuniary results of the change in the system of teaching in the medical department are said to be favorable this year. Whereas in two previous years there had been a considerable deficit, the accounts of last year show a surplus of over three thousand dollars. This, with a rapidly increasing class and a strong indorsement from the public in the shape of a handsome fund subscribed for a new building, make the future unusually promising.

THE DOCTRINE OF HEREDITY.—Mr. Galten, in his recently published work, *English Men of Science, their Nature and Nurture*, gives the number of notable relatives of each grade which scientific men on the average possess. Thus, 100 scientific men have 28 notable fathers, 36 brothers, 20 grandfathers, and 40 uncles. The influence on the paternal and maternal lines is found to be approximately equal. Thus 100 scientific men have 34 distinguished relatives on the paternal side and 37 on the maternal.

AN invention has been patented in England, by Mr. T. Harding, which is intended to prevent the entrance of sewer-gas into dwellings. Connected with the main sewer is a pipe two inches in diameter, and at the top of the pipe is a ball, so fixed that it allows an aperture of a quarter of an inch all round, through which the sewer-gas may escape from the pipe. Running up outside of the large pipe is an ordinary gas pipe, and just underneath the ball at the top of the sewer pipe a set of burners is so arranged that when lighted they make a complete circle of fire. The ball prevents the sewer-gas from rising through the centre, and it cannot escape through the flame, which entirely surrounds the aperture. The consequence is that the sewer-gas mingles with the ordinary gas, and is consumed, adding, it is said, greatly to the brilliancy of the flame. The invention may be easily applied to the public lamps, and we are informed that a one-inch pipe may be used, and that the increase in the illuminating power that would be thus gained is enormous. Another advantage is that the ball and the upper part of the pipe soon get intensely hot, and the heat draws the foul air from the sewers, leaving them perfectly free.

A good deal of laughter was occasioned in the French Chamber the other day, when Dr. Testelin, in demanding a school of medicine for Lille, in addition to those proposed for Lyons, etc., declared that the number of doctors had decreased in the town that he represents, while the population had increased. The doctor appeared astonished at the amusement caused by this statement.

The following comparisons in reference to street cleaning is from a statement made to the Philadelphia Board of Health, December 28th. Paris, with a population of over 2,000,000, with 578 miles, or 8,138,240 square yards, of paved street surface, and containing over 162,000 buildings—conceded to be the cleanest city in the world—receives 365 sweepings per year, at a total net cost per year of \$170,000, or for each sweeping, \$466. New York, containing a population of at least 1,000,000, and having 270 miles, 3,801,606 square yards of paved street surface, and 70,000 buildings, receives about an average of 104 sweepings per annum, at a cost of \$850,000, or for each sweeping, \$8,173. Philadelphia, having a population, say of 750,000, 143,000 buildings, 456 miles of paved streets, or 6,335,000 square yards, receives (on liberal estimate) 12 sweepings per annum, at a cost (salaries not included) of \$327,000, or, for each sweeping, \$27,250.

DR. W. R. GILMORE, ambulance surgeon at the Reception Hospital in Ninety-ninth street, died on Friday, the 29th ult., at the hospital, from the effects of a very curious wound, received on the Sunday previous, when he was walking out in the neighborhood of the hospital with the House-Surgeon, Dr. Goelet. The sidewalks were very slippery from the snow-storm, and Dr. Gilmore slipped and fell. The point of the umbrella which he was carrying entered his eye, inflicting a painful and dangerous wound. He walked back to the hospital, and was attended by Prof. Jas. R. Wood and others, until his death, as above stated. The deputy coroner, on examination, decided the cause of death to be compression of the brain and fracture of the orbital plate.

SIR HENRY THOMPSON has resigned the office of surgeon at University College Hospital, London.

DR. R. W. TAYLOR has been elected a Corresponding Member of the Society of Natural Sciences and Medicine of Dresden.

DR. LIONEL BEALE has undertaken the duties of Professor of Physiology in King's College, London, left vacant by the appointment of Dr. Rutherford to the University of Edinburgh.

NEW MEDICAL DICTIONARY.—The Messrs. Longman, of London, are making arrangements for the publication of a Dictionary of Medicine, in one volume, under the editorship of Dr. Quain.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, Feb. 8.—New York Ophthalmological Society; New York Medico-Historical Society.

Tuesday, Feb. 9.—Adjourned Meeting of the Medical Society of the County of New York. "The Tumors of the Optic Nerve," Dr. Hermann Knapp. Exhibition of a trocar, designed especially for ovariotomy, aspiration, and transfusion, by Dr. Simon Fitch. American Microscopical Society; Yorkville Medical Association.

Wednesday, Feb. 10.—New York Pathological Society.

Thursday, Feb. 11.—New York Laryngological Society; Brooklyn Pathological Society; Jersey City Pathological Society.

Friday, Feb. 12.—Medical Library and Journal Association. "Analyses of One Thousand Cases of Skin Disease, with Remarks on Treatment," Dr. L. D. Bulkley. Harlem Medical Association.

Saturday, Feb. 13.—New York Medical and Surgical Society.

Medical Society of the State of New York.

SIXTY-NINTH ANNUAL MEETING.

FIRST DAY—MORNING SESSION.

The Society met, pursuant to statute, at Albany, on Tuesday, February 2d, 1875, at 11 o'clock A.M., in the Common Council Chamber.

The meeting was called to order by the President, Dr. George J. Fisher, of Sing Sing, and a prayer was offered by the Rev. Doctor Bartlet.

INAUGURAL ADDRESS.

The President then delivered his inaugural address, embracing a variety of topics of interest to the Society and the profession throughout the State. Referring to the rapid growth of medical literature he mentioned the fact that over four hundred and fifty medical journals had at one time or another been published in the United States and Canada, the majority of which had lived an average of about five years. He had no doubt that a lack of nerve-centres had a decided influence upon their viability, nor of the fact that there were many yet in existence which would ere long fulfil their natural destiny. He next referred to the growing tendency to specialism; deprecating the disposition on the part of so many young men to devote their attention solely to the cultivation of some well-defined branch of practice, to the neglect of all others, which physicians he chose to term "one-organ men." No doubt the chief reason for such a course, was that they witnessed on the part of older men who had rendered themselves eminent in some particular branch, a degree of success in both a pecuniary and a professional sense which had been denied to the general practitioner. He recommended that the Secretary should be granted the privilege of sending not more than fifty copies of the published Transactions of the Society to medical journals for notice; and further, that as a mark of respect to the deceased members of the Society, memorial leaves, with suitable inscriptions thereon, should be introduced into the volumes of Transactions to be published in future.

Referring to the numerous laws relating to the medical profession, which had been passed by the Legislature, many of which modified or did away with antecedent ones, he proposed that in order to correct the uncertainty which has resulted as regards the nature of the laws actually in force, some measures should be taken by the Society for their thorough codification.

The law passed last year was mentioned, and some features of the British Registration Law pointed out, and the President suggested that a law something similar to the latter might meet all the needs of society in this country, viz., the information of the public as to who were qualified practitioners.

Two other topics, which he had at first purposed mentioning in the annual address, were of such importance that he thought best to call the attention of the Society to them at the earliest hour practicable, in order that the proper action might be insured, viz., the time and place of meeting of the Society, and the election of permanent members. Regarding the first, he thought that the Society had fully determined that the time for holding its meetings could not be more unseasonable. As for the place, there was less to be said in favor of a change, although for many reasons it might be desirable. The desirability of changing

the mode of electing permanent members was considered by the President at considerable length, and the custom of electing honorary members was likewise referred to. Lastly, the President advocated the abolition of the so-called annual address, in addition to the address at the opening of the session, as imposing a heavy burden on the presiding officer, and consuming valuable time which might better be used in other ways.

DR. A. JACOBI moved the appointment of a committee to consider the suggestions of the President, with instructions to report on the same at as early an hour as possible, especially that portion relating to changing the time and place of meeting.

COMMITTEES.

The following committees were then appointed by the President:

On the President's Address.—Dr. A. Jacobi, Bates and Jenkins.

On Credentials.—Drs. Wm. C. Wey, Thomas F. Rochester and Thompson Burton.

On Arrangements and Receptions.—Drs. F. Hyde, Wm. H. Bailey, and N. C. Husted.

Business Committee.—J. V. P. Quackenbush, D. B. St. John Roosa, and Ellsworth Elliot.

On Ethics.—Drs. Thos. Hun, E. Krackowizer, and J. G. Adams.

HYSTERICAL AMBLYOPIA.

DR. D. B. ST. JOHN ROOSA, of New York, next read a paper on "Hysterical Amblyopia, with Concentric Limitation of the Visual Field," the whole of which will be published in a future number. A discussion followed, in which Drs. A. Jacobi, Squibb, Matthewson, and Pooley joined: the former calling attention to the distinction to be made between hysterical and simulated diseases.

A communication was read from Governor Tilden, inviting the Society, its guests and the members of the Albany Co. Med. Soc., to the executive mansion on the following evening. On motion, the invitation was accepted.

Several papers, including a biographical sketch of the late Professor James McNaughton, of Albany, were read by title and referred to the Committee on Publication.

STRANGULATED HERNIA.

DR. HYDE read a paper on strangulated hernia, and was followed in discussion by Dr. Squibb, who called attention to intoxication by conium as a means of producing relaxation of the muscular system to a degree which favored taxis.

DR. GOVAN moved the appointment of a committee to invite the Governor, State officers, and members of the Legislature to be present during the sessions of the Society. Carried.

Dr. Paddock, of the Massachusetts State Medical Society; Drs. Morgan, Newton, and Rogers, of Vermont, and Dr. Hoar, of Maine, were presented, after which the Society adjourned to 3.30. P.M.

FIRST DAY—AFTERNOON SESSION.

The Society having assembled pursuant to adjournment, the President announced the following

COMMITTEES.

Committee on Nomination of Officers for the Ensuing Year, 1st District, Dr. Thomas Addis Emmet; 2d, Dr. J. Foster Jenkins; 3d, Dr. S. Oakley Vanderpoel; 4th, Dr. Thompson Burton; 5th, Dr. Alonzo Churchill; 6th, Dr. Wm. C. Wey; 7th, Dr. F. Hyde; 8th, Dr. E. M. Moore.

Committee to invite the officers of the State government to be present at the meetings: Drs. William Govan, Thompson Burton, and Arthur Wolfe.

FOREIGN BODIES IN THE EYE.

DR. T. R. POOLEY, of New York, read a paper entitled "Foreign Bodies in the Eye." He detailed several cases illustrating the modes of production and effects of such injuries, together with the method of operating. Enucleation of the injured eye was insisted on as the only safe way of preventing sympathetic inflammation of the sound eye when we were perfectly sure of the presence of a foreign body of any sort which we are not able to remove.

DR. VEDDER, of Schenectady, related a case, the results of which he thought opposed Dr. Pooley's opinion of the necessity for enucleation:

A man, while chipping steel, had a fragment enter his eye. Blindness, opacity of the crystalline, and pain followed, and he (the doctor) gave an unfavorable prognosis. In three or four months, however, the crystalline was absorbed, and with the aid of a proper glass the man could see. He believed that the foreign body remained in the eye, and the absence of unfavorable results was owing to its becoming encysted.

DR. AGNEW, of New York, quite agreed with the writer of the paper on the necessity for enucleation under the circumstances he mentioned. He believed that the form of sympathetic disease induced in a fellow eye, even when the trouble is not in the ciliary region, is so insidious and intractable that the only way to prevent loss of sight in the uninjured eye is to remove the diseased organ.

DR. ROOSA, of New York, did not consider the absorption of the crystalline, as mentioned by Dr. Vedder, a sufficient cure, nor could he consider it justifiable to leave the injured eye with its foreign contents *in situ*.

DR. VEDDER said the case came under his observation twenty years ago, and had as yet had no consecutive trouble.

DR. CHAPMAN, of Medina, mentioned a case reported in THE MEDICAL RECORD of May 1, 1873, by Dr. Knapp, in which a diseased ball had been removed. The patient had been seen by him the day before, and had suffered no return of the affection.

TREASURER'S REPORT.

DR. CHARLES H. PORTER, Treasurer, submitted his report, which was referred to an auditing committee composed of Drs. Ferguson, Mynders, and Lewis.

SUB-PERITONEAL CYSTIC TUMORS.

DR. J. V. P. QUACKENBUSH, of Albany, read the histories of two singular cases of what he called "sub-peritoneal cystic tumor."

In the first a tumor presented posteriorly to the cervix uteri in a woman in labor, and was gradually forced downwards in front of the child's head. When punctured it yielded a considerable quantity of serum, and relieved the labor of an obstacle to its completion. The second case was a young woman, who had, not long before the doctor saw her, arrived in this country, with a history and symptoms that strongly indicated pregnancy. A careful examination proved the fallacy of this supposition as well as that of ovarian tumor. The patient died, and a cyst was found between the abdominal walls and the peritoneum lining it, which contained a large quantity of clear fluid. The uterus and its appendages were normal and healthy.

DR. A. JACOBI, of New York, commenting on the

novelty of these cases, said that there appeared to him to be but two or three ways of explaining them; one was the occurrence of hemorrhage, the hemorrhagic mass being encysted, the clot absorbed, and only a serous fluid remaining, but in such case we would have the coloring matter of the blood remaining. Another cause would be the closure of a gland duct and accumulation of the secretion in quantity to form a cyst, but he was unaware of any glandular organs in these localities. The third and most probable cause was connected with errors in fetal development; of these some anomalous development of the cords of Muller, he thought, might be the most probable cause, but declined to give any decided opinion.

TREATMENT OF UTERINE FIBROIDS.

DR. THOMAS ADDIS EMMET, of New York, read a very practical paper on the "Treatment and Removal of Fibroids from the Uterus by Traction." The interesting point in the paper was the mode of formation of a pellicle in these cases.

DR. BENEDICT, of Onondaga, discussed the paper.

DISINFECTION AND SALICYLIC ACID.

DR. S. O. VANDERPOEL, of New York, read a portion of a paper on "Disinfection and Disinfectants," and was followed by

DR. E. SQUIBB, of Brooklyn, who presented to the Society a very valuable paper on "Salicylic Acid," a new product of the action of carbonic acid on phenol, which is just commencing to excite a great deal of attention as a disinfectant and anti-ferment.

DR. CASTLE, of New York, mentioned the price for which the acid, made by Kolbe's process, is being sold in Dresden.

PAPERS READ BY TITLE.

The following papers were read by title, and on motion, referred to the Committee on Publication:—

"Fracture of the Skull with Depression, followed by Hemiplegia; Result of Trephining in Remedying the Paralysis." By Dr. R. W. Pease, of Syracuse.

Report of Dr. H. S. Chubbuck, Delegate to the American Medical Association.

Report of Dr. Hiram Corliss, of Greenwich, Washington Co., Delegate to the Maine and Massachusetts State Medical Societies. Read in full, together with a communication from the "Veteran member," regretting that ill-health prevented his attendance.

On motion of Dr. Vanderpoel, the President was requested to telegraph the sympathy of this Society to Dr. Corliss.

DR. ED. H. PARKER offered a petition of an aggrieved member. It was referred to the Committee on Ethics.

On motion, it was decided to meet Wednesday morning, at half-past nine o'clock.

Recess until half-past seven.

FIRST DAY.—EVENING SESSION.

PATHOLOGICAL CHANGES IN NERVOUS DISEASES.

The Society met as agreed, at half-past seven, to listen to a paper by

DR. JOHN P. GRAY, of Utica, on "The Pathological Changes that Occur in Nervous Diseases, especially Insanity." The most notable features were the use of the term "fatty involution" to express a variety of degenerative changes, and the illustration of the pathological conditions mentioned in the paper, by means of macro-photographs projected by means of a calcium light upon a screen. After interesting the audience for an hour and a half, he was followed by a lecture by

DR. LOUIS ELLSBERG, of New York, on

ACOUSTICS.

Many interesting experiments were made to illustrate the production of sound, its character as regards pitch, *timbre*, the mechanism of the human voice, etc. Both gentlemen received a unanimous vote of thanks, and the Society adjourned at ten o'clock, to meet on Wednesday morning at the hour appointed.

SECOND DAY.—MORNING SESSION.

The Society met pursuant to agreement, at half-past nine o'clock, and the meeting was opened with prayer by the Rev Anson J. Upson, of Albany.

MISCELLANEOUS.

THE COMMITTEE ON RECEPTION AND ARRANGEMENTS reported that the following additional members had arrived and were present by invitation: Drs. S. S. Ellis, Schenectady; H. W. Bourne, of Otsego; E. G. Crittenden, Clifton; E. Clark, of Sandy Hill; L. F. R. Chapin and R. J. Eddy, of Glenn's Falls; C. B. Richards, of Broome County; J. Dunn, of Lodi; S. P. Bates, of Malone; T. L. Gibbs, of Washington County. Also the following: Drs. John W. Mitchell, of Providence, R. I., State Medical Society; M. C. Edwards, of Connecticut River Valley Medical Association, of Saxton, Vt.; and Dr. Chapman, of the Connecticut State Medical Society. The report was received and the gentlemen introduced to the Society.

The minutes of Tuesday's session were then read and approved.

DR. E. SQUIBB, senior censor for the Southern district, reported they had examined for license, Dr. Ezra S. McClellan, and recommended him for a diploma, and that he be now declared a licentiate of the Society. The report was adopted.

EXPERIMENTS ON ANIMALS.

PROF. DALTON, of the New York County Medical Society, then addressed the Society on the subject of experimentation on animals for physiological and scientific purposes. He said that eight years ago Mr. Henry Bergh, of New York, commenced in a series of newspaper articles, an onslaught on the practice, and it was subsequently followed up by the introduction of a bill in the Legislature for the organization of the Society for the Prevention of Cruelty to Animals. The Medical Society, in 1867, had memorialized the Legislature and procured a modification of this bill, so that experimentation on animals in the interests of science had been continued. Last summer, however, Mr. Bergh had renewed his attacks on the practice, as before, in a series of newspaper articles, published in the *New York Evening Post*, and his evident object was to place the Society under the control of himself and agents. The speaker then referred to the importance of the practice in determining the nature of various diseases, and the favorable results that have been realized, and urged that the Society take some action reaffirming the action of the Medical Society in 1867. With this object in view he offered the following:

Whereas, A renewed attempt has been made during the past year to excite in the public mind a prejudice against the practice of experimentation on animals for medical and scientific purposes; and

Whereas, Intimations have been publicly held out that the Legislature will be applied to for power to suppress or interfere with experiments of this nature, notwithstanding that such interference is expressly forbidden by the existing law, and in opposition to the declared sense of the medical profession; therefore

Resolved, That this Society hereby reiterates the opinions and conclusions on this subject embodied in its memorial to the Legislature, adopted February, 1867, and reaffirms its conviction of the usefulness and propriety of experimentation on animals; also

Resolved, That the President of the Society be instructed, if it should become necessary, to transmit a certified copy of this preamble and resolutions to the two branches of the Legislature and to the Governor of the State of New York.

A discussion followed, in which Drs. B. F. Sherman and Squibb participated, and the preamble and resolutions were adopted unanimously.

DR. J. G. ADAMS stated subsequently that he had held some conversation with Mr. Beach, the attorney of Mr. Bergh, and was informed that the latter had no intention of making an application to the Legislature for a change of the law; he was content to carry on the war with Dr. Dalton in the newspapers.

DR. VANDERPOEL believed that this was only a change of *venue*; that finding the profession ready and able to oppose him successfully, he was intending to interest public opinion in the matter so that the law may eventually be repealed.

Drs. J. F. Kendall, Moreau Morris, and B. F. Sherman were named a committee to invite the Health Committees of the Senate and Assembly to be present at the afternoon session of the Society, to hear the report of Dr. Bell on Drainage in this State.

THE PRIZE ESSAYS.

DR. THOMAS F. ROCHESTER, from the Committee on Prize Essays, reported that but two competitive papers had been received for the McCosh prize on the designated subject for 1875, viz.: "School hygiene in reference to the Physiological Relations of Age and Sex to Mental and Physical Education." One of these had the motto, "The quality of the brain is the key to human knowledge," and was a good, practical, common-sense article, well worthy of publication. The other bore the motto, "Salut populi—suprema lex," a scholarly and philosophical essay, for which the prize was awarded to Alexander Hutchins, A.M., M.D., of No. 796 De Kalb Avenue, Brooklyn. No essays were received for the Brinsmade prize.

EFFECTS OF NITRATE OF SILVER ON EPITHELIAL AND GLAND CELLS.

DR. MARY PUTNAM-JACOBI delegate for the Medical Society of the County of New York, read a paper entitled, "Effects of the Nitrate of Silver on Epithelial and Gland Cells," accompanied with microscopic preparations. The paper embraced references to the literature of the subject, and detailed the results of numerous experiments on animals and freshly removed portions of human tissues.

DR. HENRY D. NOYES, in discussing the paper, referred to the assistance rendered by the nitrate of silver in the study of the structure of the cornea.

UTERO-GASTROTOMY.

DR. J. MARION SIMS, of New York, made some very interesting remarks on the subject of "Utero-Gastrotomy;" saying, that having had the honor of reading a paper at the last annual meeting on the removal of intra-uterine fibroids by enucleation, he now proposed to speak of the removal of larger uterine fibroids by abdominal section, whether intra-uterine, interstitial, or extra-uterine in character. This operation is now on its trial. It stands where ovariectomy did twenty years ago. It has the same opposition to encounter, and will doubtless achieve the same victory. In this country it has been performed suc-

cessfully by Kimball, Burnham, Boyd, Storer, Darby; in England by Charles Clay, Fletcher, and very recently by Lawson Tait. Köberle, of Strasbourg, has cured four out of six cases, while Péan, of Paris, gives us the minute histories of eleven cases, with seven cures, and since the publication of his work, his pupil Urdi has published a work in which he says, that the whole number of Péan's operations up to the present time is twenty, with fifteen cures.

Dr. Sims has recently operated twice for the removal of the uterus, with large fibroid, by abdominal section. The first case was in a feeble state from excessive loss of blood. During the separation of a large fold of intestine from the surface of the tumor, the capsule of the tumor was torn up, large venous sinuses were opened, and the patient suddenly lost about sixteen ounces of blood. She never rallied, and died from the shock and loss of blood in thirty-five or forty minutes after the operation.

The second case had lost large quantities of blood and was quite anæmic, but was thought to be a favorable case for operation. It was done on the 19th of November, according to Péan's method. The patient died in seventy-six hours, of septicæmia. Examination, post-mortem, showed the pedicle in a sloughing condition below the wire clamp; the slough extending along the line of incision in the abdominal parietes, and on the top of the bladder, and in the broad ligaments. There were eighteen ounces of bloody serum in the peritoneal cavity. Péan's method of operating is to make a pedicle of the supra-vaginal portion of the cervix, and to draw this out through the lower edge of the abdominal section by clamp, as in ovariectomy. He transfixes the cervix by a double wire, ties one on each side of the cervix, inclosing the broad ligament on its respective side in the wire. Dr. Sims employed Péan's method in both his cases, but would not use it again; but he advocates the use of the actual cautery. He exhibited a clamp *à crasur* on the principle of Nott's [and Isaac E. Taylor's], by which he would compress the broad ligament on one side near the body of the uterus, and then sever the ligament with the cautery down to its junction with the cervix. The same method is to be followed on the side, and then it only remains to cut the tumor from the supra-vaginal cervix and cauterize the surface. The several cauterized portions are then dropped into the peritoneal cavity, when, in spite of the eschar, they unite at once by adhesive inflammation to the surfaces with which they lie in contact.

Dr. Sims then exhibited an automatic alcohol blow-pipe for heating the cautery irons.

Dr. E. M. MOORE, of Rochester, said his views with regard to operations which required the opening of the abdominal cavity had, for several years, been undergoing considerable change, and there seems to be some truth in the idea that it may be as safe or safer to perform gastrotomy for uterine than for ovarian tumors, owing to the adhesions which are so likely to exist in the latter case.

While it is no trifling matter, or an operation to be done without good and urgent occasion, surgeons have to a great extent got over the fear of opening this cavity. A large number of the unfavorable results are undoubtedly from septicæmia. Since Kimball, of Lowell, performed the first operation of this character, this procedure has probably been resorted to more often than the profession were aware. In the case of Dr. Kimball the patient recovered. Last summer Dr. Moore said he had a case of uterine fibroid on which he operated successfully, in which the tumor weighed seventeen pounds. The operation was a modification

of the one introduced by Prof. Miner, of Buffalo, in cases of ovariectomy, and called by him ovariectomy by enucleation.* In this case a pedicle was created by separating a portion of the serous membrane from the surface of the uterus and tumor and bringing it into the abdominal wound, where it was retained, as in ovariectomy, and formed a cup which received the blood which might escape, and the discharges, and thus prevented their entrance into the abdominal cavity.

PROFESSOR E. R. PEASLEE, of New York, called attention to some points in Dr. Sims' remarks. His own experience with this operation commenced one week after Dr. Kimball made his operation. The success or failure of the operation would depend upon a variety of causes, and was at best, even in the opinion of Dr. Sims, a dangerous one. Péan does not operate indiscriminately, but he has operated in a case of fibrocystic tumor even when the woman was nearly exhausted, and in some cases of fibroma with ascites, even when the patient was nearly moribund. Dr. Peaslee had seen but two cases in which he thought the operation was advisable, but did not wish to be understood as opposing it. He was perfectly willing to undertake it when the indications were fulfilled.

Dr. HURD, of Brooklyn, wished to ask Dr. Sims if he was aware of any objection to the use of the galvano-cautery in the separation of the mass.

Dr. SIMS declared his readiness to use it, but, at the same time, would not neglect to put a clamp on the broad ligament to prevent hemorrhage.

Dr. WALTER KEMPNER, delegate from Wisconsin, and formerly attached to the Utica Asylum, was introduced and made some remarks.

DISEASES OF THE EYE.

Dr. C. R. AGNEW, of New York, read a paper on "Certain Diseases of the Eye," and their treatment by a modified operation by canthoplasty.

Dr. GEO. T. STEVENS, of Albany, reported a "Case of Sarcoma of the Ciliary Body."

RELATION OF URINE TO SKIN AFFECTIONS.

Dr. L. D. BULKLEY, of New York, an invited guest, read a paper on the "Relation of the Urine to the Diseases of the Skin."

MISCELLANEOUS BUSINESS.

Dr. A. JACOBI, chairman of the Committee on the President's Address, presented the report.

The Committee deprecated the disposition on the part of specialists to publish so many journals devoted solely to their branches. This could not but have the effect of diverting from well-established journals, devoted to general medicine and surgery, matters which ought to claim the attention of general practitioners. A few special journals were all that were required, and these might be of the nature of reviews, in which one could find the summary of current literature on special subjects, such as therapeutics, etc.

Regarding the tendency on the part of young men to practise specialties, the committee were equally decided. The tendency was to degrade the general practitioner in the estimation of the public. It was too often forgotten that most of our men who have become eminent in certain branches, were doctors before they became specialists.

The proposition of the President respecting the appropriation of not more than fifty copies of the Transactions for circulation among leading medical journals at home and abroad was approved; as was likewise

* See Trans. of the Society for 1872, p. 187, and *Buffalo Med. and Surg. Journal* of June, 1869.

the suggestion regarding memorial leaves to be incorporated in the Transactions; and suitable resolutions to that effect were, subsequent to the reading of the report, adopted by the Society.

The necessity for a codification of the laws relating to the profession was at the present stage of the existence of the Society, of very great importance, and the committee recommended that the matter be placed in the hands of a competent lawyer. Observations were made on the inefficiency of the law passed by the Legislature at its last session, and the suggestion of the President that an effort should be made to establish a law like the one in operation in Great Britain, endorsed.

The points of chief interest in the report of the committee related to the time and place of meeting, and the election of permanent members. Respecting the first, the committee recommended that the time of meeting be changed to the third Tuesday in June, and that a committee be appointed by the Chair to take measures, if necessary, to insure the acquiescence of the Legislature in the change.

After an animated discussion, a resolution to that effect was carried.

The resolution offered by the committee, that all delegates who should serve and attend for four consecutive years, should be eligible for, and should be declared permanent members, was also discussed at length. On motion of Dr. S. O. VANDERPOEL, all that portion of the address which related to delegates and permanent membership, was referred to a committee composed of the Chair and two other members, with instructions to report at the next annual meeting. Carried, and the Chair appointed the committee as follows:

Drs. Fisher, of Sing Sing, and Hutchinson and Prout, of Brooklyn.

Dr. HUTCHINSON, of Brooklyn, called attention to the fact that for two years the names of Drs. Prout and Seeger, of Brooklyn, had been omitted from the published lists of persons eligible for permanent membership, and asked that care should be taken that they are included in the next list, and that they should be marked as eligible since 1872.

PAPERS READ BY TITLE.

The Business Committee reported the following papers by title:—

Memoirs of Andrew F. Little and U. G. Bigelow, by Dr. Levi Moore.

Report of Dr. Salvatore Caro, delegate to Pennsylvania State Medical Society.

Report of Robert Newman, delegate to New Jersey State Medical Society.

Resolutions of the Kings County Medical Society.

The Society then took a recess to half-past 3 P.M.

SECOND DAY—AFTERNOON SESSION.

The Society was called to order at half-past three o'clock, by the Vice-President, Dr. H. Jewett.

Dr. WILLIAM GOVAN, of the committee appointed to invite the Governor, Lieut.-Governor, and members of the Legislature to take part in the deliberations of the Society, reported that the committee had performed the duty assigned them. The report was accepted and the committee discharged.

UNUSUAL DISEASES OF THE ORBIT.

Dr. HENRY D. NOYES, of New York, read a paper entitled "Cases of Disease of the Orbit of Unusual Character or Severity."

Among other cases the doctor mentioned some in

which total blindness of one eye had resulted from falls upon and injuries of the frontal prominence. The doctor thought that the blindness in these cases was caused by the force of the blow being transmitted by the orbital plate to the optic foramen, at which point the concussion of the optic nerve was so great as to destroy its ability to transmit luminous impressions.

Dr. HUTCHINSON, delegate from the Rhode Island State Medical Society, was introduced.

Dr. A. N. BELL read a portion of the report of the Committee on Hygiene, embracing selections from the reports of the following counties, viz.: Albany, Cayuga, Chautauqua, Erie, Genesee, St. Lawrence, Montgomery, Ontario, Saratoga, and Kings.

The report was discussed by Drs. Kendall and Govan.

EMBOLISM AND DIPHTHERIA.

Dr. A. M. VEDDER, of Schenectady, gave the history of three cases, as follow: "Embolism of the Central Artery of the Retina," "Embolism of the Axillary Artery," "Diphtheria with Tracheotomy."

Dr. BURGE, of Brooklyn, deprecated too early resort to tracheotomy in croup or diphtheria. Many cases, he thought, were able to recover without the resort to so hazardous an expedient. He had seen cases recover without the operation, in which death seemed imminent, and, on the other hand, had seen twenty-three operations, with but one recovery.

Dr. A. JACOBI protested against allowing a patient to suffer where the operation would give him relief at once. The operation he considered to be by no means dangerous, nor was the presence of a simple hard-rubber trachea tube in the windpipe a source of any serious trouble. If superficial ulcerations of the mucous membrane occurred, they were quite as much a result of the influence of the disease upon the constitution of the tissue as of the presence of a tube. He would as soon think of declining to open the trachea of a child suffering from imperfect oxygenation of its blood as a result of narrowing of its glottis, as he would hesitate to cut down a man hanging by a rope about his neck, because it *might* be too late to restore him to life.

Dr. HUTCHINSON, of Brooklyn, expressed his belief that the operation of tracheotomy was not, *per se*, a dangerous one. It is true that we cannot tell in many cases of croup if death will result, but he was decidedly in favor of giving the patient the benefit of whatever good could come from the procedure.

STRICTURE OF THE MALE URETHRA AND ITS CURE.

Dr. FESSENDEN N. OTIS, of New York, next read a paper on "Stricture of the Male Urethra and its Radical Cure." The doctor reiterated the opinion formerly expressed, that "the slightest encroachment upon the urethral canal at any point in its course was cause sufficient to prolong an existing urethral discharge, or even to establish it *de novo* without venereal contact," and also that "the associate of stricture in every case is chronic urethritis."

The opprobrium medicorum, he said, rests upon stricture because, after the patient is pronounced *cured* by his surgeon, he is obliged to continue the systematic use of dilatation by means of a bougie or sound. Dr. Otis expressed his belief in the *true* curability of stricture, and proceeded to explain the principal causes of failure in previous methods of treatment. Among the chief reasons was the fact that heretofore strictures have been dilated, or rapidly distended, or divulsed, or divided up to a purely imaginary and arbitrary standard. The true view to take of a case is, that the calibre that nature furnishes is suited to the patient's own

person, and no one can guess at this matter. It is only to be known by an examination of the healthy portions of the canal, and a comparison of its diameters with the contracted part. The meatus urinarius has often been taken as this standard, but no opening of the body is so variable in its relations to the passage to which it gives entrance. As the result of numerous measurements, the doctor had found a pretty certain relation to exist between the size of the urethra and the circumference of the flaccid penis, and a number of average measurements were given: for example, a penis three inches in circumference in its flaccid state would have a canal that would admit at least a bulbous sound of 30 of the French scale.

Circum. of penis in inches. 3½ 3½ 3¾ 4 4¼ to 4½
Calibre of urethra (French scale) 32 34 36 38 40

In every case, he said, the measurements were rather over than under these estimates.

An improved urethrometer was shown, by means of which the exact dimensions of the canal at any point can be determined, and an urethrotome for the complete division of strictured portions; a guard upon the blade of the latter served to protect the healthy mucous membrane, while the contracted bands were brought against the edge of the instrument. A probe-pointed bistoury for use in accessible portions of the canal was also shown.

Dr. Otis reported in this paper one hundred cases, comprising two hundred and three operations upon two hundred and sixty strictures, showing the various points of statistical interest. Among other facts the following were mentioned. Respecting the seat of the stricture:

50	were	in	the	first	¼	of	an	inch	of	the	urethra.
63	were	¼	to	1½	of	an	inch	from	the	meatus.	
48	"	1½	"	2¼	"	"	"	"	"	"	
47	"	2¼	"	3¼	"	"	"	"	"	"	
26	"	3¼	"	4¼	"	"	"	"	"	"	
11	"	4¼	"	5¼	"	"	"	"	"	"	
6	"	5¼	"	6¼	"	"	"	"	"	"	
6	"	6¼	"	7¼	"	"	"	"	"	"	

The following were the measurements of the urethra in one hundred cases:

Circumference of urethra in millimeters. } 22, 28, 29, 30, 31, 32, 33, 34, 36, 37, 38, 40.

No. of cases, 1, 3, 1, 18, 26, 20, 3, 15, 1, 2, 6, 1. Not noted 2.

Thirty-four cases of over one hundred strictures, treated by the method of complete division up to the normal calibre of the canal, and which were re-examined at intervals varying from three weeks to three years, showed no tendency to recontraction.

Perfectly relieved for a time, recontraction of stricture re-examined.	8
Not re-examined.	40
Perfectly relieved and still under treatment.	3
Relieved of most of the symptoms, some symptoms remaining.	3
Partial relief.	2
Result not known.	5

In two hundred and three operations no death had occurred. Five cases of urethral fever had been observed. Only one of them had occurred when the anterior portion of the canal was the part operated on, and this was in the case of a malarial subject.

In conclusion, Dr. Otis insisted upon the necessity of enlarging a contracted canal up to its normal calibre, which calibre should be determined by actual measurement, and that no surgeon should be satisfied

with dilating a stricture up to an arbitrary or imaginary standard, or until it was "about right."

Dr. HUTCHINSON, of Brooklyn, remarked that the method of treating strictures advocated by Dr. Otis, if the true one, is one of the most important advances made in surgery in many years.

Dr. BURGESS, of Brooklyn, wished, at this point, to remark that some years ago he had presented to this Society an instrument for the dilatation of stricture. Subsequent observation had convinced him that it was not worth the snap of his finger.

The Business Committee read by title the report of Dr. Eugene Beach, delegate to the Connecticut Medical Association, which was referred to the Committee on Publication.

PERITYPHLITIC ABSCESS.

Dr. J. W. S. GOULEY, of New York, read a paper on "Perityphlitic Abscess, due to Perforation of the Appendix Vermiformis, together with Remarks on the Subject of Treatment thereof." The paper was based upon the notes of twenty-four cases, of which the following were not mentioned by either Drs. Lewis, Bull, or Buck, in their papers on this subject, viz.:

Of Dr. Kelsey's, 1.* Dr. Whital, 1,† Dr. J. C. Hutchinson, 2,‡ Dr. H. Bonticou, 2,§ Dr. C. A. Leale, 2,|| Dr. J. H. Pooley, 1,¶ Dr. J. W. S. Gouley, 1.

Dr. Gouley's case was a man, aged thirty-seven, who had for some time been the subject of hernia, for the relief of which he wore a truss. He frequently suffered from attacks of tenderness, in consequence of which he was often obliged to remove or change his truss. He came under the doctor's care in June of 1873, for treatment during an unusually prolonged and intractable attack of this sort, when his wife reminded him that two years before he had swallowed a fragment of a tooth. He had at that time a swelling in the right iliac fossa, which, after an interval of improvement, became larger, extending over towards median line of abdomen; fever and delirium supervened, and in August it opened spontaneously. No foreign body was noticed in the discharged matter. Improvements which occurred at once resulted in cure in December. In Feb., 1874, another attack occurred. A consultation was held with Willard Parker, and after a time the tumor was opened freely. A careful examination was made, without resulting in the discovery of a foreign body. The patient recovered without the recurrence of his hernia.

As a result of the study of this, and the history of the other cases reported, Dr. Gouley believed that when a spontaneous discharge of the contents of the abscess occurred, the opening should be enlarged sufficiently to permit a thorough exploration and emptying of its cavity, and that when opened artificially, it should not be done before the seventh day. In a subsequent statement, the doctor called attention to the necessity for the removal, at the same time, of the diseased appendix.

Dr. THOS. F. ROCHESTER, of Buffalo, said that it had been his misfortune to have between fifteen and twenty cases of this sort in his practice, thirteen of which ended fatally. In these examined the foreign body was found in the majority, either in the appendix or escaped. The mass was often not a foreign body, properly speaking, but a collection of phosphates derived from the secretions of the intestine, mixed and coated with faeces. He thought it very rare that foreign or other bodies got into a healthy appendix,

* MED. RECORD, Dec., 1874. † MED. RECORD, May, 1874.
‡ Communicated. § Trans. N. Y. State Med. Soc. for 1873.
|| Communicated. ¶ Communicated.

and thought that there were almost always previous catarrhal symptoms.

DR. ERNST KRACKOWIZER, of New York, gave his experience in this affection, saying, among other things, that the appendix sometimes becomes fixed by inflammation, when the movements of the intestine are sufficient to produce its dilatation and consequent admission of foreign bodies.

He cited the case of a boy who had fecal fistula into the bladder and said that the inflammation sufficient to cause the disturbance may have been during the fetal life of the patient.

GALL-STONES.

DR. J. V. KENDALL, of Baldwinsville, presented ninety-six biliary concretions removed from the gall bladder of a patient who, during life, had no symptoms which indicated the nature of her case.

AUSCULTATION OF THE OESOPHAGUS.

DR. LOUIS ELSBERG, of New York, gave the Society a short description of the method and uses of "Auscultation of the Oesophagus," and was followed by Dr. Hutchinson, of Brooklyn, who mentioned a case of a child who had swallowed a coin, in which auscultation, by the method spoken of by Dr. Elsberg, indicated the seat of the obstruction.

DR. SQUIBB asked what course would be pursued with prize-papers. If the Society reserved the right of publishing them, or allowed the writers, as in the case of other papers, to publish them at their option?

THE PRESIDENT decided that the latter course was consistent with the by-laws.

DR. E. M. MOORE, of Rochester, exhibited to the Society the extremities of two ulne from cases of fracture of the wrist—one was removed at the time of the injury and was the specimen shown by him at a meeting of the Medical Society of the County of New York, in 1873. The other was removed a short time since from a patient who had about six or seven years before had the peculiar fracture, which Dr. Moore has before called attention to. Both cases showed the nature of the injury as regards the separation of the triangular ligament for the pit of the styloid process, bringing away a scale of bone and converting the process into a sharp point, which punctures the annular ligament or has the latter bent sharply over its apex.

The Society then adjourned to meet in the Assembly Chamber at eight o'clock, to listen to the annual address of the President.

SECOND DAY.—EVENING SESSION.

The Society met in the Assembly Chamber at eight o'clock, to listen, agreeably to custom, to the President's annual address.

Referring to the various subjects which had been considered by his predecessors, Dr. Fisher chose for his paper the history of the Society since the first steps were taken towards its organization in 1796 in Saratoga County. For the history of its early years he acknowledged his indebtedness to the account left behind him by the late Dr. John Stearns, who was one of the founders of the Society and served as its Secretary and Treasurer for eleven years, and as its President from 1818 to 1821 inclusive. At first a Society of twenty-one physicians which lasted but a year, its successor in 1805 was the nucleus about which the present organization was gathered. At the commencement the adjoining counties of Washington and Montgomery joined in the organization, and William Patric, John Stearns and Patrick Howell were appointed commissioners to procure the passage of a law of incorpora-

tion. Twenty counties united at once, and at the present day all but the four of the sixty counties of the State are represented in the Society, viz.: Alleghany, Hamilton, Putnam, and Wyoming. The first meeting was held on the first Tuesday of February, 1806, and the law of incorporation was passed soon afterwards.

The attendance at the first meeting was twelve; the fourteenth, twenty-five; on the forty-second year, fifty; at the fiftieth meeting, one hundred, and during the past eight years has averaged two hundred and fourteen. The Society has now nearly five hundred living members and delegates. Many facts of interest were mentioned in connection with the subject of "Presiding Officers."

The first series of Transactions up to 1831 was published by the Society—and has since been republished in abstract form by the State. The second series, published by the State, extends from 1850 to 1872 inclusive. They by no means did the Society the credit they should have done and proved, so far as the Legislature was concerned, "the least valuable of campaign documents." The third series, published since 1773 by the Society, he hoped would be a decided improvement on its predecessors. He has made a synopsis of the literary matter since 1807 which would serve as an index to the valuable papers which had been presented. The President urged the importance of greater attention to literary work on the part of the members, and advised those who had not already done so to devote a room to their library and study apart from their business office as calculated to favor the development of studious habits.

He also remarked the want of extensive and accessible medical libraries. The library of the State has but a few medical works; the New York Hospital Library, though most accessible, is the property of a close corporation; the Medical and Surgical Library at Washington, with its 23,000 volumes and 3,000 pamphlets, is practically inaccessible, and there is an urgent want of a library like that of the Smithsonian Institute, from which books are loaned according to the character of the borrower and the nature of the work.

The President mentioned some of the evils that retard the progress of scientific medicine, deprecated the use of the "elixirs" which are so extensively advertised, and which he characterized as "slightly medicated diffusible stimulants."

Considerable attention was given in his address to considering the tendency to over-refinement and subdivisions of medical and surgical practice, which he strongly opposed, as he did likewise the establishment of so many special journals and dispensaries. The subjects of fees and homoeopathy were treated briefly, together with several others of minor importance not enumerated.

At the close of the address, the members and guests, to the number of three hundred or more, adjourned to the house of Governor Tilden, and after presentation to the Governor and his family, partook of an elegant supper.

THIRD DAY.—MORNING SESSION.

The Society being called to order at half-past nine o'clock, the meeting was opened with prayer by the Rev. Dr. Bridgman.

THE PRESIDENT announced that the committee to wait on the Legislature in reference to the subject of change of time of meeting would be Dr. Quackenbush.

DR. SQUIBB understood that the Society had an organic right to change its time of meeting without reference to the Legislature.

The PRESIDENT said the Society had to give notice of its intention.

The Committee on Arrangements and Receptions reported a list of delegates and invited guests present.

The Committee on Ethics, through Dr. T. Hun, reported that they had entertained the complaint of J. C. C. Dove, of Dutchess County, and for want of other than *ex parte* evidence, declined to act. It appeared to them that the County Society in question had not been duly notified.

DR. E. H. PARKER, of Poughkeepsie, said that he was aware that the County Society had been duly notified in the manner required, and urged that some action should be taken at the earliest possible moment, since, until facts to the contrary were known, the petitioner might be the aggrieved person.

DR. ELIOT moved that the report be referred back to the committee with power.

DR. PARKER was quite willing that this course should be pursued, but objected to the "with power." The case, he thought, was an important one, and the decision might establish a precedent; therefore, he thought the decision of the question should rest with the Society. Dr. Eliot accepted Dr. Parker's amendment and the motion was carried.

DR. KENDAL, Chairman of Committee to invite the Health Committee of the Legislature, reported that they had discharged that duty, and on motion their report was accepted.

The Committee appointed to audit the Treasurer's account reported that it had been found correct as per vouchers presented.

On motion of Dr. Eliot, the report of the committee was accepted.

DR. SQUIBB hoped that some light might be had on the item of the account which mentioned the payment of three hundred dollars for several thousand copies of the *Sanitarian*. He was not prepared to say that it was unauthorized, but thought that it was an irregularity which needed an explanation for the information of the Society, since the report of the Committee on Hygiene had not appeared in the annual Transactions.

THE SECRETARY, DR. BAILEY, said that the gentlemen would remember that the report of the Committee on Hygiene was the feature of the evening meeting of the Society last year, and the need for its early publication led to the motion of Dr. Gray, on the morning of the last day, that the Secretary be empowered to cause its separate publication and distribution to the members of the profession in the State. Dr. Bell's offer to furnish 3,000 copies of the *Sanitarian* containing the report for the amount named, and undertake as well to send it to all the members of the county societies throughout the State seemed the most economical and expeditious way of accomplishing this, and it was in this way that the item of the account was to be explained. Because of its circulation in this manner the report was omitted for the volume of Transactions.

DR. BELL, the editor of the journal in question, explained that he had fulfilled the contract as he had agreed to do, although at a pecuniary loss to himself, since the report nearly filled the journal to the exclusion of other matter and the price he received for it did not equal, by one-half the cost of publication. On motion of Dr. Elliot the treasurer's report was accepted.

ELECTION OF OFFICERS.

The Committee on Nominations then reported the list of officers, delegates, etc., for the ensuing year of which the following are the most important items:

OFFICERS FOR THE ENSUING YEAR.

For President.—Dr. Thomas F. Rochester, of Buffalo, *Vice-President*, Dr. Ellsworth Eliot, of New York, *Secretary*, Dr. E. R. Hun, of Albany, *Treasurer*, Dr. Charles F. Porter, of Albany.

Censors.—The list of censors remains about the same as last year, with the exception that J. C. Hutchison, of Brookline is appointed in place of E. R. Squibb, in the Southern district, and C. C. Wyckoff, of Buffalo, in place of L. B. Coates of Batavia.

Committee on Correspondence.—The same as last year.

Committee on Statistics.—The same as last year.

Committee on Prize Essays.—Henry W. Dean, of Rochester, Thomas F. Miner, of Buffalo, Wm. S. Ely, of Rochester.

Committee on Publication.—A. E. M. Purdy, and Ellsworth Eliot, of New York, and E. R. Hun, of Albany.

Committee on By-Laws.—The same as last year.

Permanent Members Elected.—First District: A. Jacobi, and J. W. S. Gouley, of New York. Second District: J. Hasboureck, Port Ewen; J. H. Pooley, Jr., Yonkers. Third district: Joseph Lewi, Albany; M. H. Barton, Troy. Fourth district: U. L. Snow, Canajohaire; Asael Perry, South Easton. Fifth district: Chas. D. Budd, Turin; Geo. W. Cook, Otego. Sixth district: John K. Stanchfield, Elmira; C. B. Richards, Binghamton. Seventh district: Judson C. Nelson, Truxton; Eben O. Smith, Yates Co. Eighth district: Thos. D. Strong, Westfield; Wm. S. Ely, Rochester.

Honorary Members Elected.—S. W. Oakley, Elizabeth, N. J.; J. M. Da Costa, Philadelphia, Pa.; Ezra M. Hunt, Metuchin, N. J.; Francesco Dichiaro, Palermo, Italy; Elisha H. Gregory, St. Louis, Mo.

Honorary Degree of Doctor of Medicine.—None.

Eligible for Permanent Membership.—First district, none. Second district: Desault Guernsey, Poughkeepsie. Third district: D. W. O'Leary, Albany; Henry March, Albany. T. S. Green, Coxsackie. Fourth district: Safford E. Hale, Essex; J. M. Rhodes, Herkimer Co. Fifth district: none. Sixth district: F. Wylie, Bath; D. W. Burge, Hector. Seventh district: W. W. Porter, Syracuse. Eighth district: None.

DELEGATES.

Delegates to the American Medical Association.—Drs. J. P. Gray, G. J. Fisher, H. W. Deane, W. C. Wey, J. Foster Jenkins, F. Hyde, C. R. Agnew, A. N. Bell, J. A. Minor, C. A. Robertson, J. V. P. Quackenbush, N. C. Husted, J. W. S. Gouley, Geo. F. Shradly, F. D. Benedict, H. D. Didima, J. C. Hutchinson, E. R. Squibb, D. B. St. J. Roosa, J. M. Sims, H. H. Chulbuck, R. B. Bontecou, G. H. Hubbard, J. Hunt, L. Elsberg, T. F. Rochester, E. M. Moore, J. G. Orton, W. W. Porter, J. P. White, W. H. Bailey, C. C. Wyckoff, L. Moore, T. A. Emmet, J. S. Mosher, C. Green, N. Niverson, G. S. Winston, J. J. Adams, J. B. Graves
Pennsylvania State Medical Society.—Drs. A. A. Crosby, S. Van Etten.
Massachusetts State Medical Society.—Drs. Ed. H. Parker, J. H. Emerson, E. R. Peaslee, J. M. Sims, E. Balch, C. A. Leale.
Connecticut State Medical Society.—Drs. E. S. Bradley, A. E. M. Purdy, N. C. Husted.
New Jersey State Medical Society.—Drs. R. Newman, A. E. M. Purdy, S. Van Etten, G. Buck, A. Jacobi, J. W. Nelson, F. P. Foster, Joseph Bates
New Hampshire State Medical Society.—Drs. M. R. Holbrook, W. Govan.
Vermont State Medical Society.—Drs. H. T. Hanks, J. G. Green.
Canada Medical Association.—Dr. A. O. Wolf.
Wisconsin State Medical Society.—L. Burton.

Censor of Syracuse Univ., Medical Department, same as last year.

The committee also presented the following Preamble and Resolution, which were unanimously adopted:

Whereas, After a continuous period of service as Secretary of this Society for ten years, Dr. W. H. Bailey feels constrained to decline the further acceptance of the office, it is, therefore,

Resolved, That the acknowledgments of the Medical Society of the State of New York are hereby conveyed to Doctor William H. Bailey for the self-sacrificing and eminently successful manner in which, by his courtesy, skill and ability he has discharged the arduous duties incident to his position; and that this Resolution be published in the proceedings of this Society.

Resolved, For the purpose of complying with a by-law of the American Medical Association, that the delegate from this Society whose name heads the list, be regarded as the member of the Nominating Committee from the State of New York in that body; and in the event of his absence, that the delegate in attendance whose name is next in order shall be chosen to that position.

On motion of Dr. Eliot, the Report was accepted, and the Resolutions adopted.

Following the election, the Committee on Prize Essays declared the following subjects to be competed for during the coming year:

For the Merrit Cash Prize—"Transfusion, Historically, Experimentally, and Critically Considered."

For the Brinsmade Prize—the subject optional with the candidate.

The President announced that the Committee on Hygiene would remain the same as last year. He also mentioned the death, in August last, of Samuel Shunway, M.D., a member of the Society.

On motion of Dr. Eliot the Society directed the retiring President to fill all vacancies that might occur in the list of delegates.

Dr. Squibs offered a series of resolutions relative to the publication of the Transactions which, after some discussion, were adopted as follows:

Resolved, That the edition of the Transactions for 1875 shall be 1,800 copies.

Resolved, That the Publishing Committee shall hold the copyright in the name of the Society, and shall invite the competition of at least two respectable publishing houses for its publication, and award the work to that house which will perform the work in the most economical way.

Resolved, That some slight improvement in binding the volume be made, so that the publication of the Society may be distinguished upon the shelves from the publications of the Legislature.

Resolved, That the Publication Committee communicate at once with the members of this Society and its constituent county societies, so far as they can be reached, to ascertain the number of copies required, notifying them of the cost of the Transactions per copy, and requiring the price to be sent to the Committee in advance, that the committee may meet its engagements with the publishers.

Resolved, That a copy of the Transactions for the last year and this be sent to each delegate from other States and societies who may have been present at the last meeting and at this, without charge.

Resolved, That a copy of the Transactions be sent to each medical library in the State, the library of the Surgeon-General's office at Washington, D. C., and to any other incorporated libraries known to have medical departments.

Resolved, That papers which are not placed by their authors complete in the hands of the Publication Committee within thirty days after the close of the session, be excluded from the volume.

Resolved, That the volume of Transactions be supplied by the Publication Committee to the members of this Society and its constituent county societies at a price not less than ten *per cent.*, nor more than fifteen *per cent.* greater than their total cost, and be sold at public sale at their option at a price not less than twenty nor greater than twenty-five *per cent.* upon their total cost.

Resolved, That the Publishing Committee be directed to present to the next annual meeting a plan for the future publication of the Transactions.

Resolved, That each member who may have paid the higher price of three dollars for the volumes of last year may, at his option, have another volume of the Transactions of last year without further payment.

HOT WATER IN SURGERY.

DR. FRANK H. HAMILTON, of New York, gave his experience in the use of hot water by immersion in the treatment of amputations and other surgical affections in the Reception Hospitals and St. Francis Hospital, in New York, during the past three years. (See former No. of the MEDICAL RECORD.)

DR. SQUIBB said that it was certainly gratifying to his complacency to have the views expressed many years ago in an article contributed to the *Amer. Journal of Med. Sciences* receive such endorsement. He offered also a suggestion which came first from French surgeons, that a small quantity of aromatic wine should be added to the water, not only because of its odorous nature but because its ingredients possessed disinfectant properties.

DR. KRACKOWIZER, of New York, had had some experience in the German Hospital in the employment of this measure and considered the use of hot water mostly restricted to the primary stage of injuries. After cicatrization had commenced, he thought the œdema produced by the heat, moisture, and dependent posture combined tended to interfere with recovery. Dr. Hamilton had spoken of the restriction of the application to the parts below the upper arm and thigh, but he knew no reason why immersion of the whole body might not overcome the difficulty when other parts were the seat of trouble. Hebra had done this in the case of extensive burns and the patients had been kept under water for weeks together.

DR. QUACKENBUSH reported that the committee appointed to wait on the Legislature had presented the subject of change of time of meeting to Hon. Mr. Husted, who had promised to see that it received early attention. The Business Committee read the following papers by title, and they were referred to the Committee on Publications.

"Case of Puerperal Convulsions, Apoplexy," by Dr. Cartwright.

"Case of Fracture of Humerus."

"Case of Gall Stones."

"Removal of Breast by Knife, and afterwards by Elastic Ligature," by Dr. Abbot.

FRACTURE AND DISLOCATION OF THE ACCROMIAL EXTREMITY OF THE CLAVICLE.

DR. SHERMAN, of Ogdensburg, narrated cases of "Fracture and Dislocation of Acromial Extremity of Clavicle."

DR. E. M. MOORE declared his interest in these cases which are truly rare. He had no knowledge of the results of this method in dislocation until two years ago. Last summer he received a letter from Dr. Price,

of Ill., reporting the successful issue. Two months later he had another case which resulted so favorably that it was difficult to tell which was the injured shoulder. These four cases were the only ones of which he had heard.

Dr. HAMILTON thought the gentlemen had not made a distinction between two varieties of this injury, one complete, where the outer extremity of the clavicle over-rides the acromion, the other, where the laxation was incomplete. Of the two, the former is, of course, the most serious, and the perfect cure questionable.

Dr. ROCHESTER had treated successfully a case of complete dislocation of sternal end, when the attention was attracted by the interference with breathing caused by pressure of the extremity of the clavicle against the trachea.

Dr. SHERMAN said that in both the cases reported by him the dislocation was complete.

Dr. SQUINN moved that Professors Hamilton and Dalton be requested to furnish the substance of their remarks to the Committee for publication in the Transactions. Carried.

MISCELLANEOUS.

The Committee on Credentials, through Dr. Wey, made the following report:

Two hundred and fifty-nine names were registered, ninety-seven as permanent members, ninety-four as delegates, and sixty as invited guests, including

3 delegates from Vermont Medical Society.

2 " " Maine "

1 " " Massachusetts "

1 " " Connecticut "

1 " " Wisconsin " and

2 medical members of the Legislature.

Dr. PROUT, of Brooklyn, hoped that the change in the time of meeting would enable the Society to occupy better room for its future meetings.

There being no further business the minutes of the morning's session were read and approved, and the Society adjourned *sine die*.

Reports of Hospitals.

BELLEVUE HOSPITAL.

REPORTS OF PRACTICE AND PECULIARITIES IN TREATMENT.

POTT'S DISEASE.—REMARKS OF PROF. LEWIS A. SAYRE.

The child had been sick about one year, and had been medicated for worms. This is very common when the disease is in the dorsal region, and arises from the fact that many of the symptoms under these circumstances are referred to the organs within the abdomen. When the disease is higher up, the patient may cough or have some symptoms which the doctor will say are due to some pulmonary disturbance.

These children will, instinctively as it were, hold their spinal column in such a manner as to prevent any motion; hence they will invariably squat down when they wish to pick up anything lying upon the floor, holding their backs as rigid as a stick. When they walk, the head is thrown back, chin forward, and they are constantly reaching out for something to catch hold of for the purpose of keeping the weight of the head and shoulders from the diseased spine; and when there is nothing which they can get hold of to give them support, they will catch hold of their thighs, and in that manner transmit the weight of the head and shoulders through the arms to the thighs, and thus to the ground. The proper method of examining these cases is, to place the child over the lap, face

down, with the arms over one leg and the thighs dropped over the other leg; then gradually "open" the child, as it were, by slowly separating its legs, as you see me doing now. In this manner you can extend the vertebral column and remove the muscular contraction which is keeping the diseased joints as still as possible, thereby relieving the patient of all pain. By removing this extension, or pressing on the ribs, upon the sides of the body, you will produce instant pain. This is a point not mentioned in the books. By pressing upon the top of the head and buttocks at the same time, pain is produced.

Pressing upon the spinous processes when the child is extended in the manner indicated, will in many instances produce no pain.

The fact that pressure can be made over the spinous processes without causing pain, is regarded by many as evidence that no disease of the bones is present. But it is the anterior part of the body of the vertebra which is affected, and when these begin to give way, the spinous processes begin to stick out, and by pressing upon them, we remove the pressure from the diseased surfaces, and the suffering of the patient is very much relieved.

The common teaching with regard to this disease is, that it is of constitutional origin; but that is not true in a very great majority of cases, for almost all of these cases can be traced to direct injury. Of this subject we shall speak fully when we reach it in the regular course.

THE LATE PROF. GEORGE T. ELLIOTT was a brilliant lecturer, and always commanded a full audience. His mastery of words was remarkable, and this, added to his natural grace, his pleasant voice and emphatic manner, made him a general favorite with the students. We recollect the first lecture he ever gave to a medical audience, and it being the first of the kind that we ever attended, the circumstance connected with it made a vivid impression upon us. It was in the Theatre of anatomy of the College of Physicians and Surgeons, when that institution was located in Crosby street. Prof. Gilman had invited him to give a preliminary course in operative midwifery, and as an introduction to that course Dr. E. occupied the first lecture in the description of the pelvis. For that purpose he had a female skeleton, which was suspended in the usual manner. At first he seemed somewhat embarrassed, hesitated not unfrequently for the choice of a word, and was not at all at his ease. In the midst of his description of the two straits of the pelvis, and while indicating their respective directions with the fingers of his two hands, he was startled by applause occasioned by the entrance of Prof. Gilman. This was the signal for a complete stop on the part of the lecturer. He blushed, bowed, ceased speaking for a moment, and in seeming despair invited Prof. Gilman to continue the lecture. Prof. Gilman looked in his peculiar manner over his spectacles, smiled at the students, then at the lecturer, and seemed to enjoy the consternation which he caused. All the while Dr. Elliott continued to blush, and evidently felt miserable. Prof. Gilman bowed, smiled, sat down, wiped his specks, looked up and said, "I only came in to hear you, sir. Pray, don't mind me." Dr. E. straightened himself more erect if possible than ever. Closed his lips for a moment, gave an appealing look to the students, and then was master of the situation. Dr. E. completed the rest of his hour with a grace and ease that astonished all present. Since that time he became one of the most accomplished lecturers on his branch in this city.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 13, 1875.

THE STATE SOCIETY MEETING.

At the last meeting of the Medical Society of the State of New York one or two important changes were made which, we doubt not, will insure the future prosperity of the organization. One of these changes had reference to the time of meeting. As we had already predicted, the Society was ready for the question, and the recommendation to change the time of meeting from February to June was carried without any difficulty. All that now remains is to secure the sanction of the Legislature, which, as it is a mere matter of form, can easily be done.

There were many good reasons why the time should have been changed to September, but the majority of the country members being in favor of June, their wishes were consulted, and the committee appointed for the purpose acted accordingly. The main objection to June was the meeting of the American Medical Association, and this objection still holds good notwithstanding the meeting of the State Society is fixed later in the month. It, however, seemed desirable that some definite time should be agreed upon, and that as far as possible a purposeless discussion should be avoided. So far, so good. But the Society has possibly made a mistake in fixing the time so explicitly. We think it would have been much better to have simply asked the Legislature to grant the authority for a change, and leave the selection of the precise time to ourselves. But it is well enough as it is; in fact any time was preferable to the month of February, the most inclement season of the year, and the one in which no comfortable quarters could be obtained in the hotels.

The question of change of place of meeting, although not acted upon, was seriously entertained by the majority of the country members. We doubt not that the time will soon come when this question will so force itself upon the Association that there will be no dodging a direct vote. There are some reasons why Albany should not continue to be the permanent home of

the Society, why those members who reside there should not occasionally be called upon to travel a hundred miles or two to a meeting. Why should their attendance at a meeting at home be entitled to the same consideration as that of a member who is compelled to take a long journey? In the matter of eligibility to permanent membership this is a great item.

A delegate who is an Albanian can very easily serve his time, while one in a distant part of the State, may, with the very best intentions on his part, find it impossible. It is not to be wondered at that the Albanians are opposed to the change. The Society has gained nothing thus far by a home in Albany. After an existence of sixty-nine years, meeting annually in that city, it has not even yet been able to have a regular meeting-hall. As for a library, it has none, and the only sign of a home in Albany other than in any other place is the large number of offices that are held by Albanians. But we are preparing to meet the main question by the transfer of some of these offices to other localities, the first move in this direction being the change of base of the Committee of Publication. As we have remarked before we are not in favor of any particular place of meeting, but merely wish to say that Albany has now no more of a claim for such a distinction than New York, Poughkeepsie, Utica, Buffalo, or Elmira. We do not now see any objection to meeting in a different part of the State each year. There is not so much of the ponderous machinery which we have accumulated in Albany to impede our movements, while there can be nothing particularly lost to the Society, save Albany influences.

The scientific character of the meeting was good. The majority of the papers came from this city, and were, for the most part, furnished by specialists. The eye subjects were in the ascendancy, although the uterus was by no means neglected, and the throat, brain, urethra, and vermiform process, each received respectful consideration. It is pleasant to consider how much of mutual benefit there is to the speaker and listener. The former has the very laudable object in view of instructing the general practitioner in high art, while the latter has the double advantage of being taught, and knowing whom to send for in consultation. Notwithstanding the great value of these papers, it was a subject for regret that some of the topics more directly interesting to the general practitioner were not presented.

The matter of vivisection was very properly introduced by Prof. Dalton, and appropriate resolutions, expressive of the sentiments of the Society thereon, were passed and ordered transmitted to the Legislature. We may now consider the matter settled, so far as any fears of adverse legislation is concerned. Although it was stated that the President of the Society for the Prevention of Cruelty to Animals had no intention of altering the law, it was best to have the State Society declare itself, as it did.

The old bugbear of permanent membership again came up for temporary consideration, and was finally referred to a Committee to report at the next meeting. There is no doubt that the work of this committee will be well performed. Two of the gentlemen on it have given a great deal of attention to the subject, and we have much to expect of them when the results of their labors during the coming year will be given.

THE MARINE HOSPITAL SERVICE.

THE bill for promoting the efficiency of the Marine Hospital Service, which we published in full in a late number of *THE RECORD*, has, we are pleased to see, safely passed the ordeal of the committee-room, and been favorably reported to the Senate for action.

We feel that we cannot too strongly express the sentiments of the profession in favor of this measure. This important branch of the service has been too long the football of politicians; and now, that such an advance as we have seen in the past four years has been made, under the able supervision of the present chief of the service, Dr. John M. Woodworth, towards placing it upon a secure professional foundation, we are each and all of us interested in securing beyond the possibility of relapse the advantage that has been gained.

We as physicians have a duty to perform in this matter that is peculiarly urgent, on account of the tardy recognition which the efforts of this handful of men had received from the profession at large. For three years they have been asking the assistance of their professional brethren in the great work they had in hand, but we fear our organized bodies have given them rather more of the cold shoulder than of active sympathy. Recently we have discovered a change in this respect, and now, with the success of their efforts, we hope all jealousy and animosity will disappear, and that all will work harmoniously towards the great end in view—professional advancement.

We notice one change made in the bill by the committee that cannot but be detrimental to all interests, we refer to the reduction of the salary of the Supervising Surgeon from forty-five to thirty-five hundred dollars.

Economy being the order of the day, it is natural that the law-makers should scan closely every outlet; but we submit that it is the part of true economy to pay well for tried ability and integrity, and in this case the record of the past four years speaks clear and loud. We beg our friends in Congress, when the measure comes up for final action, to restore the salary of the Supervising Surgeon to at least four thousand five hundred dollars.

RECOGNIZED MEDICAL COLLEGES.

WE have received a letter from our friend Prof. E. S. Dunster, of the University of Michigan, calling attention to the following statement made in the last num-

ber of *THE RECORD*, in regard to the number of recognized Medical Colleges in this country: "The number of Medical Colleges so recognized by the American Medical Association can be seen by a reference to our advertising columns." We should have said "A number of Medical Colleges," etc. We make this correction with pleasure, as we do not desire to be understood as implying that a college not mentioned in the list referred to is not recognized by the American Medical Association.

Progress of Medical Science.

THE RELATIONS IN TEMPERATURE BETWEEN THE MOTHER AND FŒTUS.—Dr. Felling has made a series of observations with the object of testing Cohnstein's suggestion of determining by the thermometer the life or death of the fœtus in utero. This was based on Bärensprung's observations, which showed that the fœtus is itself capable of generating heat and communicating it to the uterus, thus raising the temperature of that organ above that of the vagina. Consequently, when the fœtus dies the temperature of the uterus must sink. His observations seem to confirm Cohnstein's views, so that he considers that an equal temperature in the uterus and vagina may be regarded as quite sure proof of the death of the fœtus. He then discusses the explanation offered by Pfannkuch of the chill so often observed in women who have just been delivered, which is the following, viz., that the fœtus being a source of heat to the mother, the latter experiences a chill when it is removed at birth. Now it often amounts to only a slight shivering, and at most does not occur in more than from 30 to 40 per cent. of confinements. Thus Pfannkuch's explanation would imply a lowering of temperature in the interior parts of the body, the fact being that in the febrile child, as distinguished from one which is purely nervous, there is a rise and commonly a rapid rise in the temperature of the internal organs over that of the periphery. Among the author's observations it happened twice that there was a chill after the birth of a putrid fœtus; and this was in neither case due to septic influences, as the woman recovered without fever. He agrees rather with Schroeder's explanation of the chill in question, viz., that it is due to a difference between the temperature of the skin and that of the interior of the body. The internal temperature rises in consequence of the continued active contraction of the womb, which is now empty and in contracting meets with no resistance. During the period of expulsion, on the contrary, owing to the associated voluntary efforts involved, the lungs and skin are in great activity, so that the surface is warm and moist. In the repose which succeeds the act of birth the loss of surface temperature is considerable, and a chilly feeling is quite natural; and its intensity will depend largely on the sensitiveness of the woman and the state of her skin.—*Archiv. f. Gynæk., Schmidt's Jahrb.* 10, 1873.

THE DIFFERENTIAL DIAGNOSIS BETWEEN THE RED BLOOD CORPUSCLES OF MAN AND CERTAIN OF THE LOWER ANIMALS.—In a recent paper, an abstract of which was given in a previous number of this journal, Dr. Richardson of Philadelphia affirmed that it is possible to distinguish the blood of man from that of the pig, ox, red deer, cat, horse, sheep and goat, by

measurement of the red blood-corpuscles, even in dried stains upon clothing, wood, etc. That this proposition implied nothing more than a differential diagnosis may be seen from the mode in which it was stated, as well as from the writer's assertion, that in the majority of cases the object is not to determine "whether a particular specimen is human, as distinguished from all other kinds of blood, but to discriminate simply between the corpuscles of a man and an ox, a man and a horse, or a man and a sheep, and so establish or disprove the defendant's story, as to how his clothing became stained with blood." Still, he does not state whether there are not certain common animals whose blood cannot be thus distinguished from human blood, and it would be quite possible for one imperfectly acquainted with the facts to infer, that in any blood stain it may be determined by measuring the corpuscles whether the blood is human or not. The danger of this false inference being drawn from Dr. Richardson's paper has called forth an article from Dr. Woodward, in the last January number of the *American Journal of the Medical Sciences*.

Dr. Woodward makes no attempt to criticize the correctness of any of the assertions made by Dr. Richardson, but deprecates their being taken in too wide a sense. As a check upon too sanguine conclusions, Dr. Woodward's paper will doubtless have a salutary effect, and the results of original research which it exhibits give it very considerable value. The article is mainly concerned with establishing the fact that the blood-corpuscles of the dog approach so nearly in size to those of man as, in this instance, to entirely preclude the possibility of a differential diagnosis based upon measurements of the globules. It is shown that the observations of Gulliver and Weleker, which might be supposed to point to a certain, slight, though constant difference between the blood-globules of man and the dog really do not bear out this supposition when the methods employed by these authorities are carefully considered. So far as Woodward's measurements are concerned they appear to have been made in the most careful manner, aiming at an accuracy far exceeding that attained by Gulliver, and the method and instrument which he employed are described minutely. He took in all thirteen specimens of human blood from different persons and examined them both in a dry and moist state, the diameters of about fifty corpuscles being measured at each examination. In each of these measurements the great majority of the corpuscles ranged from .00024 to .00034 of an inch. The size most frequently measured was .00030 of an inch. Nine specimens of dogs' blood (different animals being used) were examined in the same way, and yielded averages which were about identical with the above. In three of the specimens of human blood, it is stated that the means were a trifle greater than any of those of dogs' blood, and two of the latter a trifle smaller than any of those of human blood. All the other means for the dog were within the range of the values found for human blood, and the majority of them were each identical, even to the last decimal place, with some one of those found for man. The greatest number ranged from .00024 to .00034 of an inch in diameter as in the former case, and the most common diameter was .00030 of an inch.

Woodward has made no other comparisons, but he refers to the researches of others, which indicate a like similarity between the blood-corpuscles of several other animals and those of man. Special mention is made of the quadruped, as well as of the rabbit and guinea pig. The blood of some other animals less common, is also alluded to in this connection.

He closes the article with the following emphatic language: "In conclusion, then, if the microscopist, summoned as a scientific expert to examine a suspected blood-stain, should succeed in soaking out the corpuscles in such a way as to enable him to recognize them to be circular discs, and to measure them, and should he there find their diameter comes within the limits possible for human blood, his duty, in the present state of our knowledge, is clear. He must, of course, in his evidence, present the facts as actually observed, but it is not justifiable for him to stop here. He has no right to conclude his testimony without making it clearly understood, by both judge and jury that blood from the dog, and several other animals would give stains possessing the same properties, and that neither by the microscope nor by any other means yet known to science, can the expert determine that a given stain is composed of human blood, and could not have been derived from any other source. This course is imperatively demanded by common honesty, without which scientific experts may become more dangerous to society than the very criminals they are called upon to convict."

PURPURINE FOR STAINING MICROSCOPIC SECTIONS.—M. Ranvier reports that he has been using this new coloring matter for the last few months, and the results he has obtained lead him to expect that it will furnish a clue to some of the obscure points in histology. Purpurine is obtained from madder, but the kind employed by him contains a slight admixture of alizarine. The fluid is made as follows: He dissolves one part of alum in two hundred of distilled water; this fluid is then heated to the boiling point in a porcelain vessel; he then adds a small quantity of purpurine triturated in a little distilled water; when a few minutes have elapsed the purpurine will be dissolved, but it is desirable to have a slight precipitate remaining which indicates that the solution is saturated—the object desired; the fluid should then be filtered while hot into a flask containing alcohol, and the amount of alcohol should be equal to one-third the amount of the hot purpurine solution. The liquid obtained in this way is of a beautiful orange-red color, and is fluorescent. It may then be preserved in a corked bottle, though, at the end of a month, there will be a slight precipitate, so that it will be better to make it fresh again.

To obtain the requisite depth of coloring, microscopic sections should be immersed in this fluid from twenty-four to forty-eight hours. The nuclei, as a rule, assume the color most rapidly, and are most deeply tinged; the fibres of connective tissue are not colored while the smooth and striated muscular tissue is a pale-red, approaching yellow. The protoplasm of the epithelial cells is very slightly colored, while, on the other hand, the nuclei are highly colored. Purpurine does not stain any of the nervous elements, avoiding the cells, their processes and the axis cylinders. Owing to this latter characteristic, M. Ranvier believes that purpurine may be able to elucidate some of the controversial points in the minute anatomy of the nervous system. He finds that the granules of the external and internal granular layers of the retina are colored bright red, and therefore he was led to believe that they are not true nerve elements.—*Archives de Physiologie*, Nov.-Dec., 1874.

NEW FRENCH MEDICAL SCHOOL.—For some time there has been a Primary Medical School at Lyons, but a bill recently passed the Assemblée Nationale to establish a full faculty of medicine. It met with considerable opposition from the schools at Paris and Nancy.

Correspondence.

THE LYING-IN SERVICE AT CHARITY HOSPITAL.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I have read with great satisfaction, in your issue of last week, Dr. Watts's "Report of the Lying-in Service at Charity Hospital for the year 1874." The very favorable results furnished are exceedingly gratifying to every lover of humanity, and the gentlemen who have had charge of the service eminently deserve the congratulations of the profession, and the public at large.

I feel it therefore to be an ungrateful task on my part to respond to the charge of "error," which Dr. Watts prefers against me for affirming that Charity Hospital was closed in 1869, on account of its having been visited by a severe epidemic of puerperal fever. I find in fact that the true date should have been 1870 and not 1869. The authority for my statement is contained in the "Statistical Tables" of the Bellevue and Charity Hospitals, published by the Department of Public Charities and Corrections for the year 1870, where may be found, at the end of the Compiler's preface, the following short, but explicit paragraph. "The Obstetrical Reports of Charity Hospital were rejected, the number of cases not being sufficient to render the statistics for publication useful. *This was due to the closure of the Lying-in Wards on account of the prevalence of puerperal fever.*" On inquiry of gentlemen connected with the Charity Hospital during the year referred to, I was told that this statement was substantially correct. Nor can I learn that it was called in question at the time, when first made, and the facts were fresh in the memories of all. I have, however, been since informed that the closure was not absolute, for that while cases of confinement ceased for a time to be sent to the Charity Hospital from the distributing office in New York, a few patients were nevertheless confined there, derived in part from the syphilitic wards, and in part from the Alms-house. In the "Report of the Medical Board of Charity Hospital" for the year 1869, Dr. Watts writes as follows: "The Medical Board have endeavored, during the past year, to establish a system for keeping accurate records of the cases treated in the Hospital, the supervision of which has been entrusted to a special committee. Although the histories have not, as yet, been kept in as satisfactory a manner as we should desire, still enough has been accomplished to make us hope that hereafter the records will be complete, and the experience obtained in this Hospital may serve as a valuable contribution to medical science." If, with the improved system of keeping the records, initiated in the year 1869, it shall appear that I have been misled in my assertion relative to the prevalence of puerperal fever in 1870, it will be my pleasure as well as my duty to confess my error. Dr. Watts states that, "If the statistics of the lying-in service at Bellevue for 1874 up to the time of its close were published, they would show an enormously increased ratio both of puerperal diseases, and of death." I have long been engaged upon this very matter, and as most careful records have been kept of every case, I shall soon have an opportunity to present such a history of that disastrous period, as may serve, I hope, to form "a valuable contribution to medical science."

As so much stress is laid upon the comparative results of the lying-in statistics of the two Hospitals, I

must strenuously object to conclusions drawn from the records of single years. The following figures will show how variable the results may be in the same Hospital in different years:

BELLEVUE HOSPITAL.		
	No. of Births.	Deaths from Puerperal Diseases.
1860	474	19 or one in $24\frac{1}{2}$ cases.
1861	459	17 or one in $17\frac{1}{2}$ cases.
1862	393	7 or one in $56\frac{1}{2}$ cases.
1863	419	6 or one in $69\frac{1}{2}$ cases.
1864	416	13 or one in 32 cases.
1865	590	17 or one in $34\frac{1}{2}$ cases.
1866	565	30 or one in $18\frac{1}{2}$ cases.
1867	561	9 or one in $62\frac{1}{2}$ cases.
1868	594	24 or one in $24\frac{1}{2}$ cases.
1869	473	14 or one in $33\frac{1}{2}$ cases.
1870	586	31 or one in $18\frac{1}{2}$ cases.

Thus in 1862-'63-'67 the results at Bellevue were far superior to those obtained in Charity during 1874 (C. H. one to $29\frac{1}{2}$ th). In the year 1869 the result at Bellevue was one death in $33\frac{1}{2}$ cases. In the same year at Charity there were one hundred cases of labor with four deaths (2 from metro-peritonitis and 2 from puerperal peritonitis) or one death in 25 cases—(*vide* "Annual Report" for 1869).

However, by way of compensation, the years 1861, 1866, and 1870, will be seen to have been so bad at Bellevue that it is difficult to indulge in boastfulness. It is interesting to note that in a continuous service of ten years, two of the most fatal years were followed immediately by others in which the exemption from puerperal disorders was extraordinary. In the ten years mentioned there were in all 5,530 births, with 187 deaths, or one death to $29\frac{1}{4}$ persons. LeFort found that out of 888,312 confinements in maternity hospitals in different parts of Europe, 30,394 died, or one death to $29\frac{1}{2}$ persons.

That out of 236 married women in Charity in the year 1874, four should have died of peritonitis, while in Bellevue out of 240 married women only two died during 1873, of the same disease, might be mentioned as a noticeable fact. In reality it proves nothing at all.

That Bellevue Hospital does not answer my ideal of a lying-in institution, I am willing to confess.

That Charity Hospital may enjoy a long immunity from puerperal disorders, I earnestly hope.

That it is not worth while for either Charity or Bellevue Hospital to exaggerate the defects of the other, is a point upon which I believe both Dr. Watts and myself can afford to agree.

Very Truly Yours,

WILLIAM T. Lusk.

47 EAST THIRTY-FOURTH ST., NEW YORK.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from January 31st to February 6th, 1875.

BENTLEY, EDWIN, Asst. Surgeon.—To proceed to Camp Bidwell, California, for temporary duty at that post, and, upon its completion, to return to his station in San Francisco, California. S. O. 11, Dept. California, January 25th, 1875.

SEMIG, B. G., Asst. Surgeon.—Instead of complying with S. O. 124, of 1874, from these Headquarters, to report to the Commanding Officer of the Presidio of San Francisco, for such duty as he is able to perform. S. O. 10, Dept. of California, January 23d, 1875.

Medical Items and News.

OUR REPORT FOR THE STATE SOCIETY.—The time required to insure the accuracy of the report of the State Society did not permit us to publish it in the preceding number, as was our original intention.

DR. JACOB D. WURTS, of Paltz, N. Y., is the Chairman of the Health Committee, of the Assembly. All the other members of the committee are medical men.

THE MEDICAL LAW.—It is understood that an attempt will be made to repeal the present law regulating the practice of medicine in this State.

RAPID CHILD-BEARING.—Dr. John Parr, of Buel, reports the following case: On March 7th, 1874, I attended Mrs. D. in labor, and delivered her of a male child, which she continued to nurse up to the birth of a second child (girl), January 17th, 1875. The age of the first child at the birth of the second was ten months and ten days.

MEDICAL PRACTICE IN 1700.—*The Chemist and Druggist* quotes, from the *History of Advertising*, the following curious advertisement of a regular London physician, found in the *Flying Post* of Jan. 6, 1700:

At the Angel and Crown, in Bassing Lane, near Bow Lane, liveth J. PEACHEY, a Graduate in the University of Oxford, and of many years' standing in the College of Physicians, in London: where all sick people that come to him, may have for Six pence a faithful account of their diseases, and plain directions for diet and other things they can prepare themselves. And such as have occasion for medicines may have them of him at any reasonable rates, without paying anything for advice. And he will visit any sick person in London or the liberties thereof in the day time for two shillings and Six pence, and anywhere else within the Bills of Mortality for Five shillings. And if he be called in by any person as he passes by in any of these places, he will require but one shilling for his advice.

A NEW CHINESE REMEDY for worms, syphilis, vomiting, and skin diseases, and possibly for any other kindred malady for which the patient may take it, is prepared as follows: Maggots are taken from privies and washed, then dried in the sun, fried, pulverized, and either made into pills or eaten in powder. We think it would be better for the Chinamen not to get these diseases.

A NEW MEDICAL PERIODICAL.—Geo. P. Putman's Sons have commenced the publication of a series of Clinical Lectures after the pattern of the Volkmann collection, so popular in Germany. The editor of the American series is Dr. E. C. Seguin, of this city. The first number contains a lecture on *Morbus Coxarius*, by Prof. L. A. Sayre. The subject is exhaustively treated, and is a valuable contribution to orthopædic surgery. The pamphlet is elegantly printed. We see no reason why such a series of lectures should not become very popular.

A SPECIMEN OF NOMENCLATURE.—*The Med. and Surg. Reporter* says: "Our chemical readers will doubtless be pleased to learn that a series of acids have been investigated by M. Hayduck. One is orthoamidotoluenesulphonic acid; and another, diazothoamidoparatoluenesulphonic acid. A knowledge of these is not indispensable to the practice of medicine. The action of tin and hydrochloric acid on nitro-bromacetamide gives rise to the hydrochloride of ethenylbromophenylenediamine."

THE BRITISH MEDICAL ASSOCIATION is to hold its next meeting at Edinburgh.

PHYSICIANS IN MONTREAL.—There are one hundred and eighty-two doctors of medicine in the city of Montreal.

CHICAGO MEDICAL REGISTER.—The medical profession of Chicago has founded a Medico-Historical Society, having for its principal object the publication of a Medical Register for that city. Dr R. C. Hamill was elected president, and Dr. A. R. Jackson, editor.

AN AFFECTING DISSECTING ROOM SCENE.—The janitor of an Indianapolis medical college was deeply affected on recognizing his mother-in-law on the dissecting table. His grief was the more poignant from the fact that he had himself carried the stolen corpse up three flights of stairs.

THE WOLF IN SHEEP'S CLOTHING.—In an inland town in California is an individual who claims to have a secret cure for diphtheria, to the sale of which he devotes his energies. This man has lately become religious [?] At a church meeting he is reported to have made a speech as follows:—"I have made up my mind to give my property to the service of the Lord. I have several thousand dollars in money, all of which I bestow on the Church. I have some fine blooded stock, especially some Black Hawk horses, all of which I give to the Church. I have also a lot of grain and farm produce, which in like manner I bestow on the Church. There is but one thing in all my possessions which I reserve for myself, and that is my celebrated medicine for the cure of diphtheria, which I will continue to sell as heretofore, for the moderate price of two dollars a bottle."

The Boston Med. and Surg. Jour., commenting on the above says: "They have a trick in Boston worth two of that; it is to treat disease at a certain home by prayer and the judicious use of medicine."

A LARGE CHILD.—Dr. J. B. Davison, of Moline, R. I. Co., Ills., writes as follows:

On the 16th of August last, I saw Mrs. D., a woman of Irish birth, the mother of three children, short, stout, and weighing 160 lbs. She had been in labor eighteen hours before I saw her. I at once applied the forceps and delivered her of a female child alive. Its weight was 16 lbs.; length, 21½ inches; circumference of thorax, 14½ inches; occipito-mental diameter, 7½ inches; occipito-frontal, 4¾ inches; bi-parietal, 4½ inches. It lived thirty-six hours and had just died when these notes were made, which is the reason why there are not other diameters given. The mother suffered little more than is common, and in four weeks was able to be about.

MORTALITY OF FACTORY OPERATIVES.—It is said by Geigel that the mortality of factory operatives and their children exceeds by nearly one-half that of the rest of the population.

VIVISECTION IN ENGLAND.—The enemies of vivisection are making a vigorous effort to prevent experiments on animals in laboratories and lecture-rooms, and a memorial on the subject is being numerously signed for presentation to the Society for the Prevention of Cruelty to Animals. Among the signatures are the names of Earl Russell, the Archbishops of York and Armagh, Dean Stanley, Canon Liddon, and Chief Justice Coleridge.

The scarcity of oysters has become so great in England, that the press is calling for a governmental investigation of the reasons for it, preparatory for the application of a remedy, if that be possible.

PROFESSIONAL BILLS.—Following an editorial in the *Medical Times* on the above subject, the editor announces the receipt of several communications. One correspondent sends from Boston a schedule of fees, which it is becoming customary in that city to have printed on the backs of the bills rendered for professional services, and is as follows:—

THE BOSTON MEDICAL ASSOCIATION, composed of the regular physicians of Boston, adopted the following fee-table, July 1st, 1864:

But it is left to the judgment of each practitioner to make any deduction from the following rates which the pecuniary circumstances of the patient may require. For each visit within the city in the

daytime.....	\$3.00.
For a visit after 9 P.M., and before 8 A.M.....	5.00. to 10.00.
(In cases of consultation or other extraordinary attendance in the night, the fee for each extra attendance shall be added to that for a night visit.)	
For a visit in consultation.....	5.00 to 10.00.
For attendance involving travel out of town, mileage shall be charged at a rate per mile, for short distances of	1.00 to 2.00.
For advice at the physician's house, according to the importance of the case, unreasonableness of the hour, or time occupied.....	3.00 to 20.00.
For vaccine inoculation.....	5.00.
For attendance in midwifery in the daytime.....	20.00.
For attendance in midwifery in the night.....	30.00.
(Obstetric operations, when necessary shall be charged in addition to the usual fee for attendance. In obstetrical practice all subsequent visits shall be charged as in ordinary cases of attendance.)	
For minor surgical operations, such as stitching wounds, opening abscesses, etc.....	5.00 to 25.00.
For major operations, according to importance.....	25.00 to 500.00.
(After surgical operations all subsequent visits shall be charged as in ordinary cases of attendance.)	

VENESECTION IN THREATENED OEDEMA OF THE LUNG.—Dr. E. H. Hamill, of Islip, N. Y., contributes the following item of experience:

Mrs. L., aged 46 years, height 4½ feet, weight 150 lbs., on January 5th. started to walk three-fourths of a mile to catch a train to New York. Felt perfectly well at starting, with the exception of a slight cold she had contracted two days before. After walking a few rods she felt some difficulty in breathing; although she walked slowly the dyspnoea increased, she was obliged to stop, and in a few minutes became unconscious.

When seen by myself her condition was as follows: unconscious; lips, face, and hands blue; pupils dilated; urgent dyspnoea, with constant effort to cough; a thin serous sputa RUNNING from the mouth; tracheal rales abundant, and easily heard at the bedside; pulse scarcely perceptible, slow; auscultation revealed abundant moist rales all over the chest. Diagnosis: congestion, with rapid oedema of the lungs; prognosis: death imminent.

Treatment.—Ten oz. dark, almost black blood taken from the arm—the effect was surprising; the tracheal rales disappeared, and the breathing became easier,

administered three qts. croton oil. In one hour the patient was conscious, all alarming symptoms gone, the next morning pronounced well.

MR. RAY LANKESTER will succeed to the chair of Comparative Anatomy and Zoology in University College, London.

LYING-IN CHARITY IN ST. LOUIS.—An association has been formed in St. Louis for affording obstetrical relief to poor women at their homes. It is contemplated to establish a lying-in hospital in connection with it as soon as funds can be obtained in sufficient amount. At present there is a board of directors, a committee of thirty ladies who investigate and report cases worthy of gratuitous relief, four physicians in different parts of the city who attend at the confinements, a consulting physician, and a physician-in-chief. The latter has charge of the central office and receives applications for relief.

THE PATHOLOGICAL MUSEUM OF THE PHILADELPHIA HOSPITAL, according to a catalogue recently prepared by Drs. James Tyson and R. M. Bertholet, is said to contain about one hundred and fifty specimens.

PROFESSOR OLLIER, who completed eighteen years of service in the Hôtel Dieu, of Lyons, on the 1st of January, went out of office in conformity with the rule which limits the term of service of visiting surgeons and physicians. As he is at present but forty-five, the enforcement of the rule results in serious loss to the institution, and deprives Professor Ollier of a field for research at just the age when his work is most valuable.

THE VETERINARY SOCIETY OF NEW YORK, lately organized, consists only of regular graduates of accredited schools. The following are the officers elected: *President*, A. Liautard; *Vice-President*, G. L. Robertson; *Secretary*, L. P. Bell; *Treasurer*, J. D. Hopkins.

MEDICAL SOCIETY OF KINGS COUNTY.—At the fifty-fourth annual meeting of this society, held January 19, the following officers were elected for the ensuing year: *President*, A. J. C. Skene, M.D.; *Vice-President*, A. Hutchins, M.D.; *Secretary*, Richard M. Wyckoff, M.D.; *Assistant Secretary*, J. D. Rushmore, M.D.; *Treasurer*, G. G. Hopkins, M.D.; *Librarian*, W. W. Ruse, M.D.; *Orator*, E. S. Bunker, M.D.; *Alternate*, J. H. Raymond, M.D.; *Censors*, Drs. J. H. H. Burge, G. W. Baker, J. S. Prout, B. A. Segur, R. M. Buel.

THE MEDICAL DEPARTMENT OF LIFE INSURANCE will appear in our next issue.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, Feb. 15.—Obstetrical Society. Academy of Medicine. New York Society of Neurology and Electrology. "The Connection between certain Lesions of the Optic Nerve and some Affections of the Spinal Cord, with special Reference to Pott's Disease," by Charles S. Bull, M.D.; "The Facial Expression of Certain Abnormal Mental States," by A. McL. Hamilton, M.D. Medico-Chirurg. Society. Pathological Society of Brooklyn.

Tuesday, Feb. 16.—New York Obstetrical Society. New York Dermatological Society. Northwestern Medical and Surgical Society. Medical Society of the County of Kings. Newark Medical Association.

Thursday, Feb. 18.—New York Medico-Legal Society. Brooklyn Pathological Society. Jersey City Pathological Society.

Friday, Feb. 19.—Medical Library and Journal Association, "Unique Cases, Medical and Surgical." Dr. E. Bradley.

Saturday, Feb. 20.—New York Medical Union.

Original Communications.

THE RELATION OF ELECTRO-THERAPEUTICS TO ELECTRO-PHYSIOLOGY.

By A. D. ROCKWELL, M.D.,

ELECTRO-THERAPIST TO THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK.

(Read before the N. Y. Society of Neurology and Electrology.)

In the winter of 1865, my attention was, in this way, called to the therapeutics of electricity. While attending at the bed-side of a patient, I met an old gentleman of whom I had frequently heard, and whose name had for years been familiar to very many of the profession in this city. Without possessing the slightest knowledge of anatomy or physiology, or the principles and practice of medicine, this person had, for thirty-five years, followed the so-called business of an electrician, and had treated an enormous multitude of people. I was amused by many of his absurdities of statement, but was thoroughly impressed by his unswerving integrity and vast experience, and I naturally desired to know more of this man's method and process in a field so little cultivated by the profession at that date.

On many occasions subsequently I carefully watched his methods of procedure, and saw him successful in desperate forms of chorea, neuralgia, and in many other forms of chronic nervous disease. The first case that in this way fell under my observation was a most severe and persistent form of apparent nephralgia. For over five months the patient—a young man of about thirty-five—had every day suffered paroxysmal attacks of pain of the most agonizing character. He had unsuccessfully sought relief in every direction. Seven applications given by this old man secured to the patient complete and permanent relief. A second case that impressed me strongly, occurred in the person of a little girl, about ten years of age, suffering from a severe form of chorea of eight months standing. She had taken medicine freely and judiciously enough so far as I could judge. Among other things, I found on examining one of her old prescription bottles that was brought for inspection, that Fowler's solution had been taken in considerable quantity. The patient was treated in the usual stereotyped manner of this operator, and within a month, and with less than a dozen applications her recovery was assured.

Here are but two out of many unwritten cases that in this way were forced upon my attention, and induced me at that time to study more closely the clinical side of electro-therapeutics. Now this man knew nothing of electro-physiology, or kindred departments, and while he had a superficial idea of the sensible effects of the constant current, he had never used it, but had confined himself to the simple faradic current.

In short, he existed as a most remarkable example, so far as concerns scientific electro-therapeutics of profound ignorance and immense experience, associated with perfect honesty of intention. He never enunciated an idea; neither had he any conception of the principle on which he worked and through which he wrought cures. He was, however, so thoroughly the master of the method that he invariably used, that the truth of the saying, "that it is not so much electricity that cures as the manner of using it," never seemed so clear as when comparing his effective manipulations with the awkward slipshod movements that are only too frequently the results of careless attempts at imitation.

This method, which under the name of *General Faradization*, is now quite familiar to the profession, I first described in the N. Y. MEDICAL RECORD, 1866, and published cases illustrative of its powerful constitutional tonic effects. Subsequently, before the New York County Medical Society, I practically demonstrated its *modus operandi*, and thus was introduced to the profession a method of operation which had, for nearly two score years, been used by outsiders with brilliant success, and which, notwithstanding our increasing knowledge and facilities, and our refined methods of application, is still, I might almost say, the cornerstone of electro-therapeutics.

It would be exceedingly ungracious, not to say absurd, for me or for any one to underrate the importance of a scientific study of electro-therapeutics, or to speak of electro-physiology as of little account in its relations to the former. I fully appreciate the immense aid that the important discoveries in electro-physiology have thus far afforded to the electro-therapist, but I do most decidedly object to that narrowness of view which refuses to accept a clinical fact, because it does not seem perfectly adjusted in its relations to known physiological laws.

If electro-therapeutics is in advance of electro-physiology, as it would certainly appear, we yet know that there are laws in electro-physiology yet to be discovered; that in all departments of science, facts are observed long before a solution is found for them, and that here as elsewhere, we should no more hesitate to accept well-authenticated therapeutical results, because an explanation is not readily found in physiology, than we should hesitate to accept any truth of science in general, because its satisfactory explanation is not immediately at hand.

In order to estimate the value of electro-physiology as a guide to the study of electro-therapeutics, and to form some conception of just how far it should tyrannize over and hold in check our clinical experiments, and the conclusions to be drawn from them, it is well on the one hand to examine in a general way some of the most important known principles of electro-physiology, and on the other to briefly consider the main methods of application.

More than a century has elapsed since the first experimental attempts to determine the degree of excitability of the cerebral hemispheres to the electric stimulus, and although Haller and Zinn had in 1756 referred to convulsive movements that followed irritation of the medullary substance of the brain, the universal testimony of all experimenters, up to 1870, was that the brain could not be excited by our ordinary methods of stimulation.

Very recently Fritsch and Hitzig, using the constant current, followed by Ferrier using the faradic, claimed to have discovered localized centres of movement in the brain—thus nearly unearthing as it were the idea substantially put forth by Haller during the previous century. This theory has been widely discussed, and has raised high expectations in regard to a modification of the old opinions concerning the localization of the cerebral faculties. Carville, Duret, and Dupuy, however, tell us that the above theory is unworthy of acceptance, since their more careful experiments clearly teach that it is impossible to "localize this or that convulsion as being the nutritive or functional centre of this or that nerve;" and at a meeting of this Society, not long since, Dupuy quite clearly demonstrated by the galvanoscopic frog and by the division of nerve fibre that the faradic current at least, when applied to the brain substance, is diffused from the cortical portion to those parts known to be excitable.

Now, in whatever light we view these investigations which have so engaged the attention of electro-physiologists; whether further experiment shall unmistakably demonstrate a centre of motion in the brain, or thoroughly disprove it, the practical gain to electro-therapeutics amounts to little.

It will still remain impossible by any external application to exclusively affect any special centres of movement or sensation.

Physiological experiment has simply taught us—and clinical experience has confirmed the teaching—that very mild currents of galvanism when externally applied will directly affect the substance of the brain, and it remains for us to utilize, so far as may be, this fact.

When we come to consider the action of electricity on the spinal cord and sympathetic, we find that here also there is ample ground for speculation, and room for a wide diversity of opinion.

It is no very difficult matter to expose the spinal cord in the living animals, and to show that the direct application of the current is sufficient to throw the muscles of the trunk and of the extremities into violent contractions. It is as easily demonstrated that if the cord be traversed for some time by the current, that portion which is under the electrical influence finally becomes insensible to all forms of stimulus—mechanical, chemical or faradic. A so-called inhibitory effect is produced. Finally, it is agreed that when the faradic current is applied directly to a certain portion of the upper part of the cord the excitation is transmitted to the cervical sympathetic nerve, and from thence to the radiating fibres of the iris which it animates; similarly by electrization of that part of the cord which traverses the fourth lumbar vertebra, it is possible to induce very appreciable contractions of the *vasa deferentia*—the bladder and the rectum.

I remarked that it was no very difficult matter to demonstrate the above phenomena, but it is exceedingly difficult to determine just to what extent it is possible to affect the spinal cord in the living man by simple external applications.

If it were possible in our treatment of disease of the cord to directly and solely localize the current, it can readily be seen what increased facilities would be ours in dealing with certain pathological conditions. This unfortunately we cannot do, but as in the application of electricity to the brain, so here we have positive evidence—both clinical, experimental, and pathological—that the galvanic current externally applied certainly penetrates to and appreciably affects the cord itself. Thus electro-physiology again confirms and renders certain the suggestions of clinical experience, and once more it remains for us to utilize, so far as may be, the truth at hand.

The effects of electrization of the exposed sympathetic nerve are so familiar as scarcely to need mention. The well-ascertained fact that the faradic current contracts the blood vessels and lowers the temperature of a part, while the galvanic augments the circulation, is further confirmed by electro-therapeutical observations. The circulation in the arterioles, it is found, is variously modified according to the direction of the current.

The ascending current, acting on a frog's web, constricts the arteries and thereby renders the circulation less active, while the descending current acts in a manner directly opposite.

It must be admitted that electro-physiology is encumbered with many inconsistencies and contradictions, which very materially impair its usefulness as a constantly reliable guide; but the above, with num-

bers of other equally well ascertained results of physiological investigation, attest its immense importance, and forcibly illustrates the possibilities of a more complete adjustment of the two departments of physiology and therapeutics in the future.

In no other portion of electro-physiology is this uncertainty more manifest than in the experiments in regard to the effects of the closed galvanic circuit on both the muscles and the motor and sentient nerves. One conclusion to which several physiologists hold is, that an inverse current applied to a frog in whom tetanic convulsions have been induced by the poison of strychnia, will dissipate the tetanus.

Mattenci endeavored to utilize this asserted power of the current in the treatment of a case of trismus, but with unsatisfactory results.

A modification of this general statement is found in the assertion of Pflüger, that the irritability of a nerve is lessened only by an inverse current of great tension, while a current of comparative mildness, having the same direction, results in an increase of irritability. The direct current, he claims, produces effects the reverse of this. The phenomenon called "Ritter's tetanus" is an illustration of a still more radical discrepancy; for this observer distinctly states that the direct current has a soothing or paralyzing effect on a motor nerve, while the inverse current increases irritability.

On the other hand, there is, as was suggested, a brighter side to the picture. The influence of tension and direction of the current over the vaso-motor nerves is a guide, more or less capricious, it is true, yet a most useful guide in our efforts to adapt methods of application to certain pathological conditions.

In the power of a current to restore the lost excitability of a nerve, and in the superiority here of the inverse over the direct, and scattered through the whole department of the physiology of electrotonus, in fact, we find sufficient groundwork on which to rear much that will enter as important truths into our system of electro-therapeutics.

It is claimed that a remedy, in order to be "indicated" in any special disease, must have certain well-known methods of physiological action that directly meet or counteract the observed pathological condition.

This is, to a certain extent, true. For the relief of a dry skin and a high pulse we resort to diaphoretics and arterial sedatives. To reduce the volume of blood in the brain we have bromide of potassium, and so on; but can anyone tell us minutely and satisfactorily why it is that quinine has a controlling influence over the manifestations of malarial poison, why iodide of potassium tends to eradicate the syphilitic poison, or why opium causes sleep? And yet quinine is indicated in intermittent fever, iodide of potassium in syphilis, and opium in insomnia; although each may at times signally fail to accomplish the desired result.

I freely admit that the special indications for galvanization of the brain, spinal cord, and sympathetic, especially the former, are not by any means so precise or well understood as are the indications for the administration of the above remedies. Perhaps they may never be, but possibly and probably the advance of electro-physiology, aided by clinical experience, will give more exactness to our knowledge.

Because we cannot localize the galvanic current in special portions of the brain; because we cannot perfectly explain or understand its physiological action on the centres of thought and motion, or why this action seems to be frequently adapted to the relief of many symptoms of cerebral disturbance; and, finally, because we cannot uniformly predict that relief will

follow the use of central galvanization in certain conditions, it should be no bar to our use of it in this way, and our acceptance of it as a useful remedy in cerebral disease, even although it cannot be said to be indicated in the full sense that a remedy is indicated, which has stood the test of years, and whose exact physiological action is known.

I am led by these considerations of some of the main points of electro-physiology, directly to the question, What methods of electrical application ought to be accepted and recognized by the profession as of incontestable value? And first we mention *localized electrization*, since it is the most ancient of all the methods, and probably the only one which is universally recognized, and against the propriety of which no dissenting voice is raised.

2d. *Galvanization of the brain*.—It is so thoroughly established that external applications of the current penetrate directly to and appreciably affect the brain, and, furthermore, it is so palpable to any one who has had much real and rightly-guided practical experience in electro-therapeutics, and whose views are not prejudiced by a too blind and devoted adherence to theoretical considerations, that such applications are often of immense service, that it would be unnecessary to advocate its utility, were it not that authoritative names were pledged to its condemnation. I cannot attempt, in a paper of this character, to consider fully the grounds of this condemnation; but a reference to some of the objections of Cyon, as put forth in his "Principles of Electro-Therapeutics," cannot fail (to say the least) to show their unreasonableness, and to carry the conviction that the learned teacher is more theoretical than practical.

3d. *Galvanization of the Spine and Sympathetic*.—Here again there can be no doubt in regard to the power of the current to penetrate to the nerve-tissues in question.

To be more specific concerning some of the opinions of Cyon, relating to galvanization of the nerve-centres—take his statement in reference to the relative conductivity of the tissues surrounding the cord, and the inference he deduces therefrom. Because the conductivity of the cord is ten times greater than that of the bones surrounding it—while the conductivity of the ligaments through the openings between the apophyses along which the current necessarily travels to reach the nerve-centre, is about equal to the conductivity of the cord—it is asserted that the current will by preference and with all its intensity act upon the cord. He further says, that if the cord was immediately surrounded by a better conductor, say muscle instead of bone—currents of great intensity would be required to affect the nerve-centre, since the flow of the electricity would be diverted by the better conducting muscular tissue. Hence, Cyon concludes that only mild currents should be used when the spine is submitted to galvanization. Such an idea as the above, coming from some less distinguished quarter—would be termed absurd to the last degree. Without any foundation in fact, or therapeutical experience, it would seem to have originated in the depths of his moral consciousness alone, and I take occasion to make this reference from the self-evident fact that the progress of electro-therapeutics may be impeded by the too dogmatic assertions, and the too refined and highly wrought deductions of the purely physiological investigator; as well as by the exaggerated reports of ignorant and credulous charlatans.

4th. *General Faradization*.—Of this method I can only say that it is to me absolutely indispensable in the practice of electro-therapeutics. Beginning with

this method nearly ten years ago, and at first confining my manipulations in electricity almost exclusively to it, I have not, to this day, seen cause to abandon its practice.

New and valuable methods of application have been proposed and adopted. Through a better and increasing knowledge of its subtle and far-reaching influence, and of the laws which regulate its action, the constant current is indicated over a wider range of neurotic affections, and alone occupies the field of electro-surgery; and yet, if I might roughly approximate the relative frequency with which I even now make use of general faradization in its most thorough form, and all other processes of faradization and galvanization, I should say that fully one-third of the cases indicating electricity are subjected to the first-named method.

There is no tonic influence in medicine comparable with it in power; there is none to which can be accorded such a wide range of application. Why then is it not better understood and more used by the profession, and especially by those who profess mastery in electro-therapeutics? Two reasons would seem to account for this neglect.

First. The time and labor requisite for its successful performance, and the unwillingness of the physician to subject himself or his patient to trouble.

Time certainly is required, and tiresome labor; and so far am I from loving labor for its own sake, that were it not that I know from long experience the impossibility of satisfactorily supplying its place by other methods, I should be among the last to advocate its importance.

Althaus, in his work on medical electricity, speaks favorably and fairly enough of general faradization; but in his estimate of the rationale of its operation, and the effects of the current on the operator—and especially when he would practically discard the method, because he conceives it to be inferior to the application of the constant current for a few minutes—falls into the natural error of one whose opinion is based on theory alone.

It is evident that Althaus has never made even an approach to a satisfactory use of the method. And not only is time and patience required, but much care and not a little skill, which comes only after repeated endeavors.

Second. Another fallacious reason for rejecting general faradization lies in the fear that its relations with electro-physiological laws cannot be fully explained. This objection has already been noticed, but I can give no better illustration of the unreasonableness of the objection, than by mentioning a case of disease of the supra-renal capsules (Addison's disease) reference to which may be found in the recent edition of Flint's Practice of Medicine. For eighteen months the patient, a man aged forty-five, had suffered from an exhaustion so complete, that he could with difficulty drag himself about.

Persistent tonic medication had failed to relieve him in the slightest degree. General faradization was, however, followed by such immediate and unusual results in approximately restoring the strength and the impaired functional activity of the various organs, that I presented the case before the Medical Library and Journal Association as proof, not of the power of the method to cure Addison's disease, but as unmistakable evidence of its remarkable tonic power. Objection was made to the presentation, on the ground first, that the case could not be one of Addison's disease; and secondly, that the method of treatment was not physiological. Concerning the first objection

it may be said that a post-mortem, two years subsequently, confirmed the diagnosis; in regard to the second objection I have nothing to remark.*

A fair survey of the entire field of electro-physiological experiments in their relations to electro-therapeutics seems to lead to the following conclusions:

First. Electro-physiology teaches us how to use electricity both in health and disease, *i. e.*, it must, to a great extent, guide us in our numerous methods of special application and in the multifarious manipulations called for in general and localized electrization.

Second. We are taught by these investigations, more correctly and minutely than by any clinical experience in the treatment of disease, the exact effects of the different manifestation of electricity on nerve and muscle.

Third. It enables us to intelligently discriminate in our selection of those pathological conditions that are likely to be benefited by electrical treatment—thereby saving much useless labor in experimental trials.

Fourth. It aids us both in diagnosis and prognosis, although it does not always fully, and frequently it fails wholly, to explain the most positive and brilliant therapeutic results.

In conclusion I would say that medical electricity is the legitimate property of the educated physician alone. On him depends the probability of its elevation and expansion, and on him as well rests the responsibility of its possible degradation and virtual destruction. In all probability its future status is secured, for it rests on foundations too solid to be easily overthrown, but it has grown and is still growing in spite of the opposition of those who would relegate its use to ignorant attendants or to the patients themselves, or who, with limited knowledge of the subject and less experience in its use, assert that their efforts and results in this special department compasses all that there is to electro-therapeutics.

A CASE OF HÆMATOMA OF THE THIGH.

TWO OPERATIONS.—DEATH.

By B. A. WATSON, M.D.,

[Surgeon to Jersey City, Charity, and St. Francis' Hospitals.]

Mrs. G., aged forty-eight, married, mother of nine children, five of whom are now living; had always been in good health previous to this illness. Her mother, aged seventy-two, is very healthy and strong. Her father died at the age of fifty, of peritonitis. Patient has one sister and two brothers now living; one sister and one brother died when very young; cause of death unknown.

In the month of December, 1870, Mrs. G. fell over an infant's bath-tub, the outer aspect of the middle third of the left thigh coming in contact with the edge of the tub. This injury immediately caused considerable pain and soreness, which lasted until the first of April following, when she discovered a small white swelling (about as large as a hickory-nut), which was slightly painful to the touch. The swelling continued to increase gradually, and soon became very painful, the pains being of a sharp, lancinating character. The patient was not able to sleep or eat well after the 1st of May, and consequently her general health began to suffer.

When I was called to see her, July 5, the patient

had to keep her bed the greater part of the day. The tumor was large and fluctuating. The only covering of the contents being the integument, which was of a dark livid hue, greatly attenuated and ready to give way, but the veins did not appear to be enlarged or more tortuous than usual. The tumor was freely opened, when more than a pint of disorganized blood, containing no coagula, was evacuated. Microscopical examination showed blood corpuscles and hæmatoidin. A further examination of the tumor satisfied me that the fluids had been contained in a sac, and, for the purpose of destroying this, tr. iodine was injected, after which the cavity was packed with lint previously saturated with the same. The discharge from the wound was of a thin dark color, resembling closely the fluid discharged at the time of the evacuation. There appeared within a few days after the incision a fungus growth, which had its origin from the sac, increasing with great rapidity, soon filling the entire cavity, and then spreading over the adjacent parts, somewhat resembling an immense rose. Hemorrhage from this fungus was at times free, but readily controlled by pressure; there was also sloughing from the same at various times. August 6, a consultation was held with Drs. Sayre and Varick, when it was determined to remove the tumor by excision. The following day I operated, with the assistance of Drs. Varick, McGill, Caldwell, Wolfe, and others. The part excised was elliptical in form, and measured, after it had been allowed to contract, nine inches in length and five inches in width; apparently not a particle of the morbid growth was allowed to remain. The wound was then closed by the use of pins and sutures. The disease had not extended below the fascia lata, and this formed the floor of the wound after the operation. For nearly two months after this operation the patient was steadily improving, and the incision had almost healed, when some pain was felt at a point near the upper extremity of the incision. The tissues at this point were somewhat discolored, thickened and hardened, and a second tumor presented itself, which grew rapidly for a week, and was then removed by the knife. This second growth was found to be beneath the fascia lata and to involve the subjacent muscular structures. The fascia was crowded up so that it was almost in contact with the integument at the point where the tumor emerged. Under the microscope the tumor exhibited well-marked stroma and heterologous cells. The second growth was not nearly so large as the first. The wound was treated the same as the previous one, and in about six weeks had completely healed. The patient remained free from pain for nearly three weeks, when it returned, being of the same character as at first. The granular system was not involved at the time of either the first or second operations, to such an extent as to be apparent during the most careful examination; neither was there any marked cachexia. The pains had been slight from the time the tumor was evacuated; the appetite had much improved under the use of tonics, and sleep was restored by freedom from suffering. There was considerable discoloration at various points in the old cicatrix, and at these points there soon appeared nodules, which rapidly increased in numbers. Her friends were now informed that the only hope, even for temporary relief in operative interference, must be found in amputation at the hip joint. The present extent of the disease would not permit an operation at a safer point. This fact they immediately communicated to her. She replied: "I am willing to submit to this danger if there is any prospect of a permanent cure." I could not promise a cure, or even a very

* The specimen, together with a history of the case, was presented before the New York Pathological Society.

long stay of proceedings. The danger of the operation was fully understood by herself and family. Their final decision was in favor of allowing the disease to take its course.

The rapidity with which the entire soft parts of the thigh became involved was truly surprising. The patient became more feeble every day, and the cachexia was soon very marked. The appetite was very slight, the sleep disturbed and unrefreshing; pains constant and severe. Death came to her relief, February 6th, 1872. An examination of the parts showed the tissue of the thigh to be wholly involved, with the exception of the femur, which was apparently sound. Through the soft tissues the finger was easily passed in any direction immediately after death.

The diagnosis of hematoma was made at the time the sac was opened, and its contents examined microscopically.

This diagnosis was based on the *origin*, physical symptoms and microscopic examination as detailed in the preceding report.

Progress of Medical Science.

JOHNSON ON THE RESULTS OF TREATMENT BY MASSAGE.—It is well-known that this method of treatment has been very popular in the north of Europe during the last few years, more especially among the Danes. They usually mean by the term massage, the use of such passive manipulations as rubbing, kneading, percussing and rolling of the soft parts, though some of the writers use it more loosely so as to include passive movements of the joints. A full description of this treatment, as applied to joints, and especially the method known as Mæzger's of Bonn, was published by Drs. Fisher and Cutter, in the *MEDICAL RECORD*, for Jan. 1st, 1874. In the *Hospitals Tidende* for Dec. 9th, 1874, Dr. Johnson has given a record of the diseases for which he employed massage, during a period of about one year and a half, and the results which he has obtained appear to mark a new era in the treatment of a certain class of affections. The following is his list of diseases with the number of cases treated, and the results.

1. Distortion. Under this term the author apparently includes sprains. He says that acute cases are rapidly cured, the slighter ones at one or two sittings while chronic cases even with considerable hyperplastic growth, may also be cured, or at least relieved by this treatment. He gives four cases, two of which were cured, one in 3 and the other in 10 sittings; while two were relieved, one in 15 and the other after 23 sittings.

2. Acute serous synovitis. The author states that this disease can always be cured by massage, and the time required will vary from a day to a month. The two cases he treated were of the knee-joint, and were caused by a luxation of the semi-lunar cartilage. One was cured by 36, and the other by 47 applications of massage.

3. Chronic serous synovitis. This disease requires great patience on the part of the physician as well as of the patient, in consequence of the enormous thickening of the capsule and the surrounding ligaments, and the atrophy of the muscles of the affected joint. Twelve cases of this knee-joint trouble were treated and all were cured but one, and in this case the patient tired of the treatment after 18 applications. In the other cases, the number of applications were from 19 to 176.

4. Hyperplastic synovitis also requires perseverance. A number of the patients tired of the treatment before much improvement was manifested. The number of cases treated was twenty-seven. Of these seventeen were cured by from 4 to 121 applications, and ten were improved by from 43 to 136 applications.

5. Tuberos hyperplastic synovitis. This disease, the author insists, can certainly be cured by massage, when there is no deeper lesion, but it is sometimes difficult to determine the absence of such a complication. The same is likewise true of granular hyperplastic synovitis. Here it is also difficult, at times, to decide whether the bones are at all diseased. In doubtful cases massage may be applied carefully, and if it does not cure it will not interfere with the subsequent performance of a surgical operation. Two cases are reported of knee-joint disease; one was cured by 270 applications, while the other was improved by 110.

6. Flaccidity of the capsule of the knee-joint. Three cases are reported, and in each both joints were affected. Two cases were cured, one by 25 and the other by 36 applications; the third was benefited by 92 applications.

7. Synovitis of tendons. Massage, the author says, is peculiarly suited for the treatment of this disease. The acute crepitating form of the disease can be made to disappear in a very short time. Even chronic cases do very well, though old cases are occasionally very stubborn. Six cases are reported, of which three were acute, and were cured by from 5 to 21 applications; the other three were chronic, of which one was cured by 153 and another by 125 applications, the third was improved after 12 sittings.

8. Myositis. This term, the author says, explains the morbid process that, in the great majority of cases, is the palpable cause of the affection called "muscular rheumatism." If treatment is commenced before the disease has existed for a long time, it can always be cured. Even in chronic cases it can be very much benefited, though often very stubborn. Nineteen cases are reported, of which eleven were cured by from 4 to 72 applications, and eight were relieved by from 12 to 160 applications.

9. Sciatica, and other neuralgic affections, when they do not have a central origin, may be cured by massage. All the cases were of sciatica, were six in number cured, with a single exception, the patient in this latter case discontinuing the treatment after the fifteenth application. The other five required from twenty-seven to fifty-two applications. Of these cases, three had resisted all other previous methods of treatment.

CONDITIONS WHICH CALL FOR THORACENTESIS, AND SOME OF THE ILL-EFFECTS FOLLOWING IT.—In an able communication on Pleuritic Effusion, Dr. Wardell thus states the morbid conditions which may be regarded as the states indicating the operation:

1. In all cases in which inspection and the physical signs give evidence of a large quantity of fluid, when there are symptoms of compression of the lung, and there is manifest cardiac displacement.

2. When there are urgent dyspnoea, an irregular pulse, and threatening of orthopnoea.

3. When the affected side is smooth and rounded, and the intercostal spaces are effaced or protrude; when measurement proves bulging; when the dulness in the chest is complete, or demarcated, and absolute; when there is abolition of tactile fremitus; when there are broncho-phonic voice, tubular breathing, and absence of breath-sound; when the patient can only lie on one side, or in diagonal position; and when there is the hippocratic sign of succussion.

4. When the exploratory needle proves the fluid to be purulent.

5. If the heart be pushed from its normal situation, and the apex be substernal or beyond the right sternal edge, or if it be thrust towards the left hypochondrium, or if it be lost; when it becomes presumptive that the organ has been driven inwards and backwards; and when, on the one side, the liver depends abnormally into the abdomen, and when on the other side the relaxed and down-pressed diaphragm so displaces the spleen that its free edge can be felt.

6. When half the thoracic cavity is filled, and a month or so shows no proof of absorption, the longer the delay the less are the chances of expansion.

7. In those exceptional cases of double pleurisy when both cavities become half-filled with effusion, and dyspnoea shows the lung-space to be dangerously encroached upon.

8. In pulmonary phthisis, where the accumulation of serous or sero-purulent secretion causes distress, and when the other lung assumes the symptoms of bronchitis or pneumonia, the operation should at once be performed.

9. In mechanical hydro-thorax it may be had recourse to, though with no object to cure, but with merely a view to prolong life, and to aid the action of medicinal remedies.

10. In children, whose chest-walls are thin, and in whom the white tissues are more developed and confer greater resiliency to the thoracic parietes, and whenever there are certain evidences of fluid, it should, without delay, be evacuated.

11. In hydro-pneumothorax it may, generally with safety and benefit, be employed.

12. Pointing externally should never be waited for.

13. Under certain circumstances repeated tappings are required.

The following facts are also introduced as illustrating what may occur in some cases.

Mr. William Date, of Crewkerne, tapped a patient, who had all the signs of simple pleuritic effusion, and was surprised to find that pus made its exit. Although the aspirator was employed, the pus that reaccumulated became offensive. The patient was tapped several times, with great relief on each occasion, but subsequently sank and died. No post-mortem was permitted.

In the *Journal de Médecine et de Chirurgie*, for December, some observations are reported as having been made by M. Peter, of Paris, at the Hôpital St. Antoine. He remarked that puncture with the trocar in purulent pleurisy is often followed by the formation of a purulent fistula. It was important not to be misled on this point, and on every occasion the patient and his friends should be forewarned. Immediately after the puncture the wound appears to close, but after a time it opens, discharges a little pus, closes again to reopen later on, and a permanent fistula is gradually formed. Unless the patient be forewarned in such cases, the physician will be probably accused of unskilful management.—*The Doctor*, January 1, 1875.

TREATMENT OF GLANDULAR SWELLINGS OF THE NECK BY THE INJECTION OF ACETIC ACID.—At the Hospital for Diseases of the Throat, Golden Square, London, Dr. Morell Mackenzie is now treating enlarged and indolent glands about the neck, especially in adults, with injections of the dilute acetic acid of the British Pharmacopœia. Seven minims is the quantity injected the first time, and ten minims or more may be used if several injections are necessary. They are made with an ordinary hypodermic syringe. One of two results may follow the injection. Either the

gland suppurates, and the pus is discharged as in an ordinary abscess, or else it disappears gradually by interstitial absorption, without any suppuration whatever. It is impossible to know beforehand whether suppuration will occur. In some cases one injection will excite suppuration, in others several are required. It is stated that by this means, those unsightly lumps, which formerly were treated for months by iodine paint and internal remedies with indifferent success, can now be removed in a few weeks with only trifling annoyance to the patient, and, at the most, with a slight scar.—*Irish Hospital Gazette*, Jan. 1, 1875.

SPLENIC LEUKÆMIA.—The January number of the *American Journal of the Medical Sciences* contains a very interesting article by Dr. Da Costa, in which he describes two cases of splenic leukæmia that were treated by the hypodermic injection of ergotine. Of these two cases, the first, which terminated fatally, is minutely reported. The more noticeable symptoms in this case were progressive emaciation, an inordinate appetite, a "sallow, unhealthy aspect," anæmia, together with the physical signs of an enormously enlarged spleen. The region of dullness extended from the sixth intercostal space down to the crest of the ilium, and from the median line in front to a line descending from the axilla. On a level with the umbilicus, the dullness extended two inches across the median line to its right. Microscopic examination of the blood showed the leucocytes to be in the ratio of one to two of the red globules. Five grains of ergotine in glycerine and water were injected hypodermically every second day, and subsequently the dose was increased from eight to ten grains. This having been continued for three weeks, the size of the splenic tumor was found to have diminished by one inch in all directions. The general condition did not, however, improve, and as the patient complained of the pain occasioned by the injections, they were discontinued. One quarter of a grain of iodine in twelve minims of glycerine and water was then injected in the same manner, and caused some further reduction in the size of the spleen, though the diminution was less than that which followed the ergotine injections. Still the patient's health did not improve, and finally a local peritonitis appeared upon the right side, which was attended with fever and intense pain, until finally death ensued from exhaustion. On post-mortem examination the spleen was found to measure 13½ inches in length, 6½ in breadth, and 4 inches in thickness. Its weight was 4 lbs. 14 ozs. Under the microscope all its elements appeared hypertrophied. The liver showed doubtful appearances of what is described as "leukæmic swelling."

In the second case the disease was of a less aggravated type. The spleen was much enlarged, giving "a dullness extending from a point in the sixth intercostal space two inches below the nipple, in a line with the anterior margin of the axilla, to a distance somewhat below the ribs; in all, a vertical diameter of six inches." Microscopical examination of the blood showed in two specimens respectively eighteen and twenty white corpuscles, in comparison with twelve and fourteen respectively of normal blood. In this case, as in the former, ergotine was injected hypodermically in the same manner. After eight injections, extending over a little more than a fortnight's time, the patient's condition had been decidedly benefited. Percussion over the spleen showed a dullness of only 3½ inches in the vertical diameter, and an examination of the blood found the white corpuscles in nearly normal proportion. The patient was discharged as cured.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, February 20, 1875.

NEWSPAPER ADVERTISING.

Newspaper advertising is beginning to get into fashion again. With the dimsy, shallow and transparent excuse of educating the public on matters pertaining to general health, the secular press is full of the utterances of men who itch for public notoriety. In many quarters not only has the ordinary modesty departed, but in its place we have the impudent defiance of the meanest quack. The Good Book tells men of every class to beware of wolves in sheep's clothing, and this advice applies at present with particular force and significance to our profession at this time, for never before have these wolves been better clothed, been more sneaking and more dangerous.

There is no disguising the fact that the object of these men is that increase in business which public notoriety will give them. The profession understand this as well as they do, but these scientific quacks are tricky enough to cover up their tracks either by a show of innocence of intention, by a pretended indignation against the paper which did them the service, or by a hypocritical regret that their honest motives should be impugned. These are taken in the light of so many apologies to their brethren for acts which they themselves know to be wrong, and they go on advertising as before.

We are aware that there are some instances in which a medical man is paraded before the public against his will and without his knowledge, but these instances are very rare indeed. His brethren are willing to acknowledge this fact, and charitably make every allowance in his favor. The general character of such men and their acknowledged respectability in the profession weigh very strongly against any suspicion of wrongdoing. But these are only occasional and isolated exceptions to the present rule of professional advertising. Such men get before the public by accident, but never by design, and suffer the infliction but once

or twice during a long professional career. These are not to be mentioned in the same breath with the professional advertisers to which we refer.

Our remarks are intended to apply to those who have no reasonable excuse for their disgraceful deeds. When we come to consider the facts in the individual cases, they can be susceptible of but one explanation. Here, for instance, is a physician whose communications to a daily paper concerning his medical doings, and his individual opinions put him in the light of a regular contributor. It is not prudent to have his articles over his own name, but such a responsibility is easily shifted upon the ubiquitous Jenkins, who, by the merest accident, appears to be on hand at the right time. The public may not understand how this is done, but the profession do. Of course our great man objects to liberties being taken with him; of course he says to the interviewer that such publications would injure his reputation with his professional brethren, but these protests are matters of form, as a part of some prospective testimony before a committee of ethics, and are so mildly and naïvely made that Jenkins understands the situation at once, and runs the risk of any personal offence. For the great man to express regret and indignation at the liberties taken with him in the next morning's issue of the paper, is another matter of form; the more frequently he is called upon to go through with it the more natural can he act his part. The profession must not call him to an account, because his protestations of innocence and his indignation at the betrayal of that innocence put him above the technical requirements of the code. Such men are now multiplying in our midst, men who have never been capable of making a reputation among their peers, but who are determined to make it with the public. They belong to a certain class, and every time they make their appearance in the newspaper columns the profession is mortified, disgusted and indignant. The act is not looked upon merely in the light of an unfortunate blunder, but as a downright act of the most conniving kind of quackery.

We have repeatedly expressed the opinion that it was the duty of the profession to elevate itself in the eyes of the public, and that one of the ways to do this was to educate the people up to the point of the requisite appreciation of our merits. But this is very different from individual advertising. In the former case the man is a leader of public opinion, in the other a quack. Our aim should be to advance the profession as a body. This cannot be possible so long as the few bold and conceited charlatans pretend to speak for it and drag it through the dust of newspaper sensationalism for their own pecuniary benefit. But these men can never be reached by reason.

A great many advertisers go even farther than this, and furnish questionable professional articles, over their own signatures, to the daily papers. One invites reporters to be present whenever he reads a paper before

a medical society, another furnishes a medical lecture or anniversary address, while another writes to say that the profession needs more education, leaving the public to infer that, as a body of men, we are too ignorant to be trusted. Naturally, the public look upon these individuals as oracles, and naturally, too, the profession wraps itself in its offended dignity and bows its head in shame.

PREMATURE BURIAL OF MEDICAL PAPERS.

If it were possible to estimate accurately the amount of ink and paper—to say nothing of brain and muscle—consumed in the preparation of the various short-lived additions to the medical literature of the day, the statistical information thus acquired would be positively startling. We have always felt a kindly sympathy for those writers whose toil and trouble over the elaboration of essays which scarcely survive beyond the period of still-birth, or merely enjoy—if enjoyment it can be—a few flickering days of extreme obscurity. Many of these papers possess a well-developed vitality, and die mainly because they are not placed in an atmosphere congenial to their growth, or they are prematurely interred in unknown graves, from absolute lack of appreciation of their inherent mental or physical force. Of this class are the various literary productions which, under the name of “Transactions” of National and especially of State organizations, find a temporary resting-place, in undisturbed repose, on the practitioner’s book-shelf, to become, in time, a matter of interest to the ragman. The contributions which they contain are literally buried alive, and soon pass into undeserved oblivion, the author alone dropping the regretful tear. There is hardly a volume of “Transactions,” in these days of advancement, but contains some paper worth preserving in the columns of a medical journal, but, in the present system of publishing, the profession at large is but little benefited. We seldom see extracts in medical serials from these annual *omnium gatherarum*, and when they do appear they have a decidedly *post-mortem* odor, on account of the still-born character of the original paper. As we have already intimated, in other phraseology, the assistance of the accoucheur and the nurse is alone needed to ensure the prolonged healthy existence of these literary bantlings; the resurrectionist has but slender hopes of success. The whole system is radically wrong, and should be speedily amended. Far better would it be to inaugurate at the earliest available moment a new rule in this respect, and in the pages of a medical journal of respectable circulation—if need be, by authoritative selection on the part of the State Society itself—give deserving contributions a prominence which they have never yet possessed.

DR. KEITH, of Edinburgh, is said to have performed ovariectomy now one hundred and ninety-six times, with the low mortality of late years of only ten per cent.

Reports of Societies.

ACADEMY OF MEDICINE.

Stated Meeting, Feb. 4th, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

PNEUMONIA, ITS PREVAILING TYPE, ETIOLOGY AND TREATMENT.

The discussion was opened by Professor AUSTIN FLINT. After a few preliminary remarks the doctor proceeded to indicate some of the various points of inquiry which suggest themselves in connection with the subject under discussion.

First. Attention was directed to the diversities which diseases present at different times and different places. There can be no doubt but that such diversities exist in all diseases that prevail epidemically or endemically. For example, intermittent and scarlet fever, in a very large number of cases, are attended with little or no danger to life, yet at certain times they become two of the most fatal of affections. This difference with regard to severity and tendency to complications, with our present knowledge, is difficult to explain. That is, whether it is due to the degree of the essential cause, or whether due to difference in susceptibility in the system. This fact, however, will apply more or less to sporadic diseases, and also to general diseases and local affections. For example, the disease under discussion presents a marked difference in type at different times and places. The disease is of much greater gravity in South than in this climate, etc., etc. Does pneumonia at the present time, as it prevails in this city, present any peculiarities?

The histories of four fatal cases were read. One case was a young man; another was an aged woman; another a middle-aged person.

In the case of the young man the physical signs were a little slow of development. In the second case patient was apparently doing well, and suddenly violent delirium set in and patient died within a few hours.

In the case of the old lady, death occurred unexpectedly, for she was laboring under a mild form of the disease. Fever was mild in one case, and high in another. Slight mental disturbance or delirium was present in all the cases.

The question of treatment was next considered.

In connection with this subject the record of a case was read which was made in 1837.

That patient was bled freely ($\frac{1}{2}$ xxx. in the recumbent posture) and took calomel and tartar emetic freely. He was taken with the disease Jan. 22d, and March 1st was convalescent. This suggests the question, was the disease controlled by the bleeding, etc. With regard to blood-letting in pneumonia, reference was made to the work of Louis and to the statistics of Dr. James Jackson, as they appear in his supplement to the work of Louis. The doctor also referred to his own cases, 133 in number, reported in 1861. The conclusions of Louis are that bleeding has a happy effect upon the progress of the disease, and shortens its duration; that this effect is much less than commonly believed, but that patients bled during the four first days recover four or five sooner than when bled at a later period.

Second. Pneumonia is never arrested at once by blood-letting. If an opposite opinion is entertained, it is because the disease has been confounded with an-

other, or because the severe symptoms have been relieved.

Louis, it seems, compares the duration in those cases in which blood-letting was performed early with the duration when the blood-letting was performed later in the disease. The question now arises, may not the bleeding performed in the latter part of the disease have tended to prolong its duration, and the difference between the cases, with regard to duration; not because early blood-letting had a tendency to shorten it, but rather that the blood-letting resorted to in the latter stages of the disease had a tendency to prolong it.

Dr. James Jackson arrives at the same conclusions as those of Louis; but the same question is pertinent with reference to his researches.

Does bleeding ever arrest pneumonia? In some of Louis' cases was there evidence that the disease was arrested.

In none of Dr. Flint's cases did the evidence appear that the disease was arrested by blood-letting.

He mentioned two cases, occurring in Bellevue Hospital, in which the diagnosis was made very early, and in which the disease appeared to be arrested by blood-letting. In these cases there may be room, perhaps, for doubt with regard to diagnosis, and then, again, the question arises, does not pneumonia of itself occasionally abort?

In considering the effect of remedies we must take into account this important fact, namely, that pneumonia limited to one lobe, and not complicated, has no tendency *per se* to fatal results. The disease kills by its complications and the extent of its invasion. The question of treatment then, resolves itself into this, do the measures adopted prevent grave complications in the invasion of more than a single lobe? If, therefore, blood-letting, or other measures of treatment, diminish the rate of mortality, this result is obtained either by directly lessening the invasion of other lobes and grave complications, or indirectly fulfilling the same object by shortening the duration. To determine the correct answer to such inquiry requires careful and conscientious men of clinical experience.

With regard to the employment of opium in the treatment of pneumonia. In the time of Louis opium was rarely employed in the treatment of any inflammation, acute in its character. Louis, however, used the syr. of poppies in the treatment of pneumonia, and regarded the influence of opium as beneficial. Reference was made to forty-nine cases in which he (Dr. Flint) has given opium quite freely. He added that he regarded it an important measure of treatment, especially in a certain class of cases characterized by vigilance, restlessness, perhaps delirium, in short, a general condition of nervous erethism.

He ventured more, that under similar circumstances, in *all* local inflammation, opium is an agent of the greatest value. It appeared, then, that the mode by which the good effect is produced, is by placing the system in a better condition to tolerate the local affection. And this is important in the treatment of all diseases which have a tendency to prove fatal by asthenia. With regard to cardiac or arterial sedatives: the value of these remedies, such as veratrum, aconite, which perhaps are preferable to tartar emetic, must be determined by analysis of cases.

Another important item in the history of the disease is the formation of heart clot. Measures, therefore, which have a tendency to prevent this accident are important. Ammonia has been used for this purpose, based upon the researches of Richardson, but he was not prepared to say how well-founded the suggestion will prove to be. He had employed digitalis, upon

the theoretical idea of giving increased power to the heart's action and perhaps in that manner diminish the liability to the accident.

Finally a new object has been presented in the treatment of this disease, namely, to diminish the condition of hyper-pyrexia. This is an object presented not upon the consideration that it is a symptom or effect acting secondarily, but that it is an agency actually destructive to life. Among the remedies to be employed for reducing the temperature of the body, quinine is prominent at the present time. Reference was made to his own analysis of cases published.

We have, however, a more potential agency in cold water, used in the form of douche, bath, or pack.

It appeared to him that the testimony is now sufficient in its behalf to warrant its use; and that it can be employed without hazard.

The question of alcoholics and alimentation enters into the subject of treatment, but it is finally well established that all cases of disease which have a tendency to destroy life by asthenia, require sustaining diet, and in many cases stimulation.

The doctor read from the *Irish Hospital Gazette* concerning what was termed by the writer "sewer-gas pneumonia." He regarded it as an important subject, and perhaps one worthy of more careful consideration than it has hitherto received.

The discussion was continued by Prof. W. H. THOMSON. He first read the histories of five cases treated in Bellevue Hospital, illustrating the antipyretic effect of cold water in the treatment of pneumonia.

These cases were very much alike, and represented a similar class of cases with regard to exciting causes, so far as temperature and climatic considerations are concerned. All had received carbonate of ammonia in ten-grain doses every two hours, and quinine in two-grain doses, good diet, and the local application of ice in ice-bags to the chest.

There was one fatal case. That patient died of pulmonary oedema. There was, however, in that case a manifest improvement with regard to lowering temperature after the application of ice, the same as in the other cases.

The ice was permitted to remain upon the chest until the temperature had been brought down to 100° or below, and then removed. This required from three to eight or ten hours, even more, and it was necessary to repeat the application once in twelve to seventeen hours. The ice was reapplied when the temperature arose.

He was not able to conceive why cold should be employed in the manner recommended by Niemeyer by means of compressors.

He was of the opinion that cold is not employed to the degree it should be on account of the manner in which it is recommended to be used by teachers of medicine. He regarded wetting the skin with a single drop of water as so much draw-back upon the efficacy of the agent employed. The object aimed at, pure and simple, is abstraction of heat, and the prolonged contact of water is a source of irritation, and the wet clothes a source of discomfort. Now, any degree of cold can be obtained by applying ice shut up in a water-tight receptacle, and thus avoid all irritation and discomfort to the patient.

The india-rubber bag, of course, is the most convenient receptacle that can be employed.

He objected to the numerical system employed by Louis, in the consideration of the comparative value of different plans of treatment, for there is scarcely a disease that we are called upon to treat that is so little an

independent disease, when we take into consideration the results and sequela, as pneumonia. For this reason, he did not think that any reliance could be placed upon records of results unless we have a record of all the possible available facts in the history of the patient. For instance, why is pneumonia so much more fatal in malarious regions than in regions where there is no such influence present?

In an extreme case of congestive chill there is a sudden enfeeblement of the heart, and after death we find the ventricles in a great state of relaxation and engorgement. From the beginning throughout, the symptoms such as feeble or absent first sound, and clear distinct second of the heart, have indicated more or less paralysis of the heart.

With this comes engorgement of the lungs, liver, and other organs of the body. We have, therefore, an influence that begins with weakening the power of the heart over the pulmonary circulation, and we can readily see how that influence may affect the results in cases of pneumonia.

Again, take a case of this kind: one in which a patient with very slight pneumonic symptoms, temperature low and amount of lung involved small, and yet the constitutional symptoms are very grave, and perhaps it is found out that the patient has had ornal disease for years, and death follows from pulmonary edema. Such points are of the utmost importance in the history of the case. Now, how much can we know with regard to the value of statistics unless we have a correct knowledge of the antecedent condition of the patient? Nevertheless, in ordinary acute pneumonia we have been led to regard the chief danger, aside from temperature, to be found in the heart, and acting upon that principle he had been using carbonate of ammonia very freely, regarding it as the most certain cardiac stimulant that can be given and continued for any great length of time. He administered it in ten-grain doses every two hours. Along with this he administered one grain of quinine every hour.

When the pain in the side is severe at the commencement, he applies three or four leeches, and that is the extent of his blood-letting. The leeches are applied to act through nervous association exclusively, and not at all upon the general circulation, which is absurd.

The quinine is administered both for the purpose of obtaining its anti-pyretic effect, and to prevent, in a certain degree, the formation of croupous exudation in the lung, and also very certainly to delay the tendency to suppuration. The application of ice is for its anti-pyretic effect.

When ice cannot be obtained he would use warm poultices covered with oil silk. This would be his routine treatment if called upon to state it.

He very much doubted whether hospital statistics could ever be made so available as are the careful statistics of private practice.

PROFESSOR LOOMIS remarked, that in discussing this question the etiology and treatment should always be associated. This is true not only of this, but of all diseases. It seem to him that we cannot treat any disease, but especially pneumonia, unless we are familiar with the cause which has given rise to its development.

With reference to pneumonia, as in other diseases, we have the predisposing and exciting causes; but of all the predisposing causes, the most important is age.

The disease is rarely met with in children under five years of age, that is, the ordinary acute pneumonia under discussion this evening. The disease is

most frequently met with between the ages of twenty and forty years, and above sixty years of age. Climate also has much to do with the disease as a predisposing cause. Poverty and intemperance again are powerful predisposing causes.

His impression was that the majority of cases of pneumonia occurred when the patient was in a condition of debility.

Now, when a state of debility is present, dependent upon almost any influence, a pneumonia may be developed, but then it cannot be regarded as an idiopathic pneumonia. He questioned very much whether idiopathic pneumonia is a disease very frequently met with, etc. It is described in books, it is true, but if a man under the influence of alcohol, or in a condition of chronic alcoholism, places himself in a position where he will be exposed to cold, and contracts a pneumonia, it is an alcoholic pneumonia that is developed. Again a man is under the influence of malarial poison, we are just now staggering under its influence, and we expose ourselves to change of temperature and a pneumonia follows, we have a malarial pneumonia; and, perhaps, the same thing may be said with regard to sewer-gas which has already been alluded to. Then, again, we have a large number of diseases depending upon a specific poison, such as septicæmia, pyæmia, rheumatism, etc.; all the list of diseases which depend upon mal-assimilation. When the exposure is made and the pneumonia is developed in such cases it is dependent upon the condition present in the system of the patient, and that condition of system must enter into the question of treatment.

Taking this view of pneumonia it appeared to him that when an attempt is made to study statistics with regard to the results of treatment, one finds himself in a forest at once. There are two important things to be accomplished in the treatment of pneumonia.

First. We are to look after and if possible find the cause. Not the exciting cause, but the condition which has preceded that and placed him in the pneumonic condition.

Second. We wish to reduce the temperature. This is an element of danger in any disease; and, when it rises high, it is the duty of the physician to resort to some measure for its reduction. When the temperature in a case of pneumonia does not rise above 103°, it was the opinion of the doctor that it might better be left alone. When, however, the temperature rises above 105° it should be reduced as soon as may be. As far as his experience went, it was against the use of cold application to the chest.

He had noticed two things in connection with this plan of treatment:

First. A tendency of the pneumonia to spread.

Second. That the tendency was towards only a temporary control of the temperature.

There are certain days upon which crisis occurs, and the temperature falls, consequently they must be kept in mind, and if the temperature falls upon those days, no matter what means are resorted to for its reduction, we cannot claim that it should be ascribed to the influence of the remedy employed at that time. It is believed that the elevation of temperature depends upon the rapidity with which molecular metamorphosis goes on in the body. Now the question arises, do we know of any means for arresting this metamorphosis? If so, then that is the remedy that should be employed.

He believes that the sulphate of quinine possesses this power, and that to accomplish this effect, it must be given in large doses. Clinically, he was certain that a temperature of 105° or 106° can be lowered one

or two degrees by a full dose of quinine, and the smallest dose that he would employ for that purpose would be ten grains. He was not certain that he had had sufficient observation to warrant him in condemning the use of cold in the treatment of pneumonia, but thus far his experience had not been favorable to its use, and for the reasons already stated. Another important object in treatment is to sustain the heart's action. As far as his observation had extended these patients die from heart failure, the heart no longer having power to carry on circulation.

He regarded such accidents as heart-clot, pulmonary œdema, cyanosis, paralysis of the bronchi, etc., as the result of failure of the heart to properly perform its work. Consequently, he regarded the condition of the heart as the cause of death in pneumonia in a great majority of cases. To sustain the action of the heart, nutrition and alcohol are the most serviceable agents at our command. It is true alcohol has been abused and injudiciously used, but when the first sound of the heart is feeble, some cyanosis is present, collateral œdema is imminent, etc., alcohol acts in a most remarkable manner, and sometimes only a few doses are required to carry the patient over the point at which failure in heart-power has manifested itself. Where the patient has been addicted to the use of alcohol, it should be administered from the beginning.

(Discussion to be continued.)

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 27, 1875.

DR. F. DELAFIELD, PRESIDENT, in the Chair.

DR. FINNELL presented an intra-uterine tumor, removed from an unmarried female, aged thirty-five, whose death was caused by pyæmia, the result of an attack of metro-peritonitis. The post-mortem examination revealed the presence of pus in the pelvic cavity.

Dr. F. remarked that the specimen was interesting in connection with the frequent attacks of uterine hemorrhage which clearly pointed to the existence of a polypus, and which latter could have been removed by any competent surgeon had he seen the case.

In this connection he referred to two similar cases of polypus which he had successfully removed by dilating the os with sponge tents.

DR. SELL alluded to a case in his experience in which dilatation was effectually accomplished by the laminaria digitata.

PYO-NEPHRITIS—GUMMY TUMOR OF CORD.

DR. DELAFIELD presented a specimen of pyo-nephritis, removed from the body of a man, æt. fifty-four, who entered the Roosevelt Hospital, January 3. He had primary syphilis twelve years before, the chancre having been followed by secondary symptoms. On the 28th of December, 1874, the first symptoms he noticed about himself was that his stream of urine was small, and finally stopped altogether, and after a day or so he suffered complete retention for thirty-six hours. From this time until his admission the catheter was employed. After admission a good-sized instrument was passed into the bladder with ease and his urine drawn off without difficulty. One week previous to admission he began to lose power in his legs, and after having been in the hospital a few days he began to pass his feces involuntarily, and was unable to walk at all. Although the paralysis was almost complete there was a considerable amount of sensation left. The urine, which had to be drawn off in con-

sequence of paralysis of the bladder, was alkaline, and contained pus and blood. The latter was so much in quantity on the 18th as to amount almost to hemorrhage. Coincident with this condition there was a marked rise in temperature, with drowsiness, and he died the next day comatose.

At the autopsy the organs of interest were the spinal cord, bladder, and kidneys. In the cord there was a gummy tumor, having its origin in the inner layers of the dura mater, involving the pia mater, and to some extent, the tissue of the cord itself. In consequence of this condition of the cord there was marked cystitis, following which was pyelitis, and lastly, the pyo-nephritis, beautifully characterized in the specimen presented by the accumulation of pus between the kidney tubules.

DR. FINNELL related the particulars of the post-mortem examination which he held upon a child aged five years, who died of cerebri-form cancer of the omentum. Death occurred suddenly as the result of the rupture of a large vein through the centre of the mass.

DR. HEITZMANN presented a specimen of catarrhal pneumonia on behalf of Dr. Lewis Smith, and described in detail the pathological anatomy of cheesy pneumonia.

COLITIS, AND FUNGOID DEGENERATION OF RECTUM.

The SECRETARY presented on behalf of Dr. John Q. Bird, of Jersey City, a specimen of colitis with stricture of the rectum. The following was the history of the case: Edward Dorrington, æt. twenty-four years, a printer, admitted to the Hudson County (N. J.) Hospital, February 10, 1874. He complained of more or less pain and diarrhœa for a year previous to admission, which prevented him from following his usual vocation. On admission, there was excessive pain over the abdomen, not increased on pressure, and obstinate diarrhœa, there being from six to twelve passages during the twenty-four hours. Following each of these there were rectal growths, having the appearance of large fungoids. These growths were reduced with much difficulty; but continuing to protrude for several months, a number of them were ligated at different times by the attending surgeons.

The urine was never examined as there were never any symptoms pointing to any particular trouble in the kidneys. Acute tuberculosis was developed about three months previous to patient's death. The diarrhœa continued until death.

Section Cadaveris.—Thirty-six hours after death body extremely emaciated. Both lungs were found firmly adherent to the chest-walls. The adhesions were dense and of a white color. There were several cavities throughout the lungs of variable size, one being as large as a small orange. Some of these were distended with a brown dirty-looking fluid of the consistence of cream, and having an intense gangrenous odor. Others contained a fluid having the appearance and consistence of pus. The lungs in various portions were studded with small indurated nodules, about the size of a pea. In the upper portion of the left lung these nodules seemed to coalesce and form a mass as large as an orange. Peritoneal membrane everywhere healthy; the stomach felt indurated towards its pyloric end, and on being cut into, it was found somewhat constricted and thickened near the pyloric orifice. The rest of the stomach and small intestines were healthy. The rectum, colon, and cæcum were more or less involved on their mucous surfaces with these fungoid

excrescences. These growths did not extend beyond the ilio-cæcal valve.

DR. DELAFIELD remarked that the appearances presented were very frequently met with after colitis.

NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

Stated Meeting, January 18, 1875.

The PRESIDENT, DR. MEREDITH CLYMER, in the chair.

DR. BEYERLEY ROBINSON read a paper "On Certain Morbid Alterations of Mucous Membrane; their Influence on Speech; and their apparent Relations with Diseased Nerve-structure."

DR. ROBINSON remarked that we were too apt to take for granted, in cases where impairment of voice is a prominent symptom, that the seat of the disease was in the vocal organs. We owe much to Dr. Morrell Mackenzie for a correct pathology and rational treatment of the nervous disorders of the larynx. Vocal asynergia may be due also to changes in the blood, as anæmia, specific poisons, as that of diphtheria, etc. Besides these there are other factors in dysphonia, which have been too imperfectly studied. First among these are the various conditions comprised under the term "catarrh." The mechanism of altered intonation from chronic nasal catarrh was commented on and explained. Tumors in the nasal passages produce the same result, though less frequently. Their presence is readily recognized. Chronic inflammation of the soft palate may give rise to paresis of the muscles and cause imperfect enunciation of certain words. It may not be manifested until after the catarrhal symptoms have disappeared. In chronic granular pharyngitis, popularly known as "clergyman's sore throat," we have at first infiltration, then atrophic tissue degeneration, and at the same time hypertrophy of the pharyngeal follicles. The frequent ulceration of these glands are due to lessened or abolished function of the peripheral nerves, from interstitial neuritis, compression being produced by the proliferated elements of the neurilemma. The tendency of neuritis, and particularly of chronic neuritis to spread by continuity of tissue to other branches of the same nerve-trunk, or plexus, will explain many of the phenomena of granular pharyngitis. A case of chronic naso-pharyngeal catarrh and granular pharyngitis was related as illustrating two facts: (1) the dysphonia which frequently accompanies this condition, though the apparent trouble within the larynx is insufficient to account for imperfect speech. (2) The good results which may follow the treatment of naso-pharyngeal catarrh. This case the writer thought substantiated the opinion, that sometimes the trunks of the pneumogastriæ, lying adjacent to the pharyngeal walls, are involved in the inflammatory processes. Dr. Robinson cited experiments by Dr. Weir Mitchell, on animals, which went to prove that many diseases which we call functional are really connected with nerve congestion, no traces of their pathological state being found after death. An affection of the voice, similar to that in chronic pharyngitis, may also depend upon chronic inflammation of the nerve-trunk. There are cases in which, though the influence of the diseased pneumogastric is evident, it is intermittent, happening only by occasional direct irritation of the pharyngeal walls. A few swallows of a bland water, as water, will modify or relieve the symptoms. From this it may be argued that anæmia of nerve-tissue on the one hand, and congestion on the other, may cause definite morbid phenomena.

The Society then proceeded to the discussion of the report of the committee "On Experimental Researches of the Motorial Functions of the Cerebral Convolution," as ordered at the last meeting.

DR. J. C. DALTON briefly recapitulated the chief points of the report. The experiments were made on five animals, and were continued for about two hours. The fact that flexion or extension of a limb would nearly constantly follow the application of the electrodes to a particular point, while no such effect would be caused by their application at a point a few millimetres removed, gave a high idea of the certainty of the result. The general agreement in the experiments of the committee and those of Hitzig were remarkable, both as to the points of excitation, and the resulting movements. Application of the electrodes to the dura mater were always followed by contractions on the same side, whilst excitation of the gray matter, with few exceptions (4 out of 169) produced contractions on the opposite side. The movements following excitation of the dura mater were of a shrinking character. In one experiment in which there remained a portion of dura mater at the posterior part of the convolutions, excitation of this fragment caused repeated movements on the same side, while excitation of the nervous matter all about it was followed by no movements.

DR. JAMES J. PUTNAM, of Boston, by invitation of the President, made a few remarks, referring briefly to some experiments performed and published some six months since, which were undertaken with a view of testing to what degree, if any, feeble induction currents applied to the cortex cerebri, after the manner of Hitzig and Fevrier, acted on parts lying beneath the surface. The method of procedure was to expose the brain carefully, and, after finding one of the so-called centres, and the minimal strength of current able to produce the muscular contractions on the opposite side of the body, to carry a sharp knife under the part, severing all nervous connections, but leaving the mechanical contact intact. When this had been done the same strength of current failed to call out the muscular movements.

DR. PUTNAM mentioned also some experiments of Dr. James, of Harvard University, which he was assisting to make, which should determine whether excitation of the cortex of the cervical lobes, where, according to Meynert and others, the various sensitive fibres of the body find their central termination, would cause a rise of blood pressure, such as is known to follow excitation of peripheral nerves. The changes in the blood-pressure were recorded through a manometer attached to some large artery, upon a revolving cylinder. The results so far had been inconstant. The experiments were still in progress.

DR. J. J. MASON thought objections might be made to the experiments of Hitzig and Fevrier with respect to the diffusion of electric currents; the galvanometer is fit only to test the diffusion of the galvanic and not of the faradic current.

After some remarks by DR. G. M. BEARD, the Society, on motion, adjourned to February 2d.

CONSUMPTION OF APPLES IN PARIS.—The Parisians devour 100,000,000 of apples every winter. An eminent French physician thinks that the decrease of dyspepsia and bilious affections in Paris is owing to the increased consumption of this fruit, which, he maintains, is an admirable prophylactic and tonic, as well as a very nourishing and easily-digested article of food.

Correspondence.

SPECTRAL ANALYSIS.

REPLY TO DR. WATERMAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Knowing the pressure upon your columns I will endeavor to be as brief as possible, and, to avoid lengthy quotations, will ask the readers of this to refer to the articles by Dr. W. and myself in the RECORD for October 15th, November 16th, and January 30th, when necessary.

Dr. W., in reply to my criticism concerning spectrum photography, states that he referred to the portion of Kirchoff's map reproduced in Roscoe, and which contains "about 130 sun-lines." Now, in his first paper he refers to Kirchoff's map in this connection, as containing "many hundreds of sun-lines." Is it surprising that I should have supposed he referred to Kirchoff's original map,* which does contain "many hundreds," etc., and not to the fragment of the map referred to in his last communication.

Dr. W., in his reply, re-asserts that some of the lines in Draper's map "are made, evidently, at the red and violet part of the spectrum." (I italicize the word red.) The following, I think, will be sufficient evidence of Dr. Waterman's error:—

"NEW YORK, Feb. 1, 1875.

' DR. H. G. PIFFARD,

"Dear Doctor:—In reply to the question in your letter of to-day, whether the map of the diffractive spectrum published by you (Dr. Henry Draper) in the *American Journal of Science and Arts* for December, 1873, contains any sun-lines at the red end of the spectrum, I would state that the map does not contain any lines of that part of the spectrum. The spectrum was in that case photographed on bromo-iodized collodion, and only the parts from *g* to *o* are represented. To speak more accurately, the lines shown in the map are from wave-length 4,350 ten-millionths of a millimetre to 3,440 ten-millionths of a millimetre.

"A misapprehension may have arisen from the statement I made in a foot-note, that "since writing the above I have succeeded in photographing the lines of the visible spectrum from *b* downwards, and the picture comprises not only the regions including *E D C B a* and *A*, but also the ultra red rays. These latter photographs have not yet been published.

"Yours truly,

"HENRY DRAPER, M.D."

This would force us to the conclusion that when Dr. Waterman looked at the "map" which Prof. Draper "has given us," he did not know which end of the spectrum it represented, and his persisting in error after I had pointed it out is certainly remarkable.

In paragraph ninth of his reply, Dr. W. *misquotes* me, as reference to the RECORD of Nov. 16th, will show. I do not, therefore, feel it incumbent to notice the four paragraphs which follow it, and which are in a measure based upon it.

I must, however, be pardoned for entering somewhat at length into the question of the instability of hemato-crystalline. I used this word, and continue to use it, in its ordinary sense, that is, to indicate the sub-

stance to which the color of circulating blood is due. That Dr. W. used the word in the same significance would appear from the following sentence in his October article, page 531: "The coloring pigment of the blood has been produced in crystalline form and is known as cruorine, hemaglobine, or hemato-crystalline." In the same paragraph he further says: "that these crystals are indestructible, preserving their crystalline structure, and other peculiarities, almost forever."

Hemato-crystalline, whether existing in unaltered blood or as isolated crystals or in solutions of them, is characterized by the fact that under some circumstances it contains more, and under others less, oxygen, and these two states are evidenced by certain characteristic spectra. Now, if absorption bands other than those peculiar to oxyhemato-crystalline and reduced hemato-crystalline appear or are in any way produced, it is universally conceded, except perhaps by Dr. Waterman, that the fact of such appearance is due to the existence of some new substance formed at the expense of, and necessitating the destruction of at least a portion of the hemato-crystalline. In my criticism I stated that exposure to ordinary atmospheric influences invariably affects it. To this assertion Dr. W. takes exception, and challenges his "critic" to find an authority to support his proposition. Foumouze* says: "L'hématoglobine est caractérisée chimiquement par son extrême instabilité."

Preyer † says: "Schr eigenthümlich sind die Veränderungen des Hemoglobin-spectrums, sowie eine Zersetzung der substanz eintritt. Nach mehrstündigen Stehen der reinen Lösung bei Zimmer temperatur ist die Farbe dunkeler," etc. Further, does Dr. W. forget that in his article in the "Archives" occurs the following sentence? "Hoppe Seyler says: 'It is a substance intermediate between hemato-crystalline and hematine, an intermediate product of the spontaneous transmutation of hemato-crystalline,' etc. Plenty of authorities might be quoted to sustain the fact known to every spectroscopist, that the coloring matter of the blood undergoes alteration when exposed to ordinary influences, and this change is evidenced by the occurrence of a new band, called by Hoppe Seyler, its discoverer, Methæmoglobin. Its occurrence in the dried blood adhering to wounds was noticed by Sorby, and Dr. Waterman, in his "Archives" article says: "Note the band on the red coincident and even overlapping the C line. It is never visible when fresh blood is examined and is therefore characteristic of old blood." Disputing the opinion of other observers who believe that this band in C is produced by some new substance, Dr. W., on page 458 of "Archives" says: "This band in red is probably due to the action of the various gases which are evolved during the process of drying." This explanation is hardly valid, in view of the fact that this band will appear in tightly-corked solutions, as every one knows.

The next paragraph of Dr. W.'s reply reads as follows: "So also must I maintain what I said in my lecture, that when the outer form of the blood-corpuscle is destroyed by chemical or mechanical means, we may demonstrate blood by producing the crystals!"

I can hardly find fault with Dr. W. for misquoting me, as referred to, when shortly after, with admirable impartiality, he misquotes himself. What he did say is as follows:—"We will find that these qualities of hemato-crystalline are of the greatest importance in medico-legal cases. When the outer form, etc., . . . it is yet perfectly practicable to produce the crystals."

* Unters. neb. das Sonnenspectrum. Berlin, 1842.

* Les Spectres d'absorption du Sang. p. 23. Paris, 1871.

† Die Bluthkrystalle. p. 49. Jena, 1871.

Now, as Dr. Waterman had not, at any previous point in his lecture, made mention of other crystals than those of hemato-crystalline, and as hemato-crystalline is specifically referred to in the immediate context, it was certainly fair to assume that the words "the crystals" referred to crystals of this particular substance, and not to something else. I think my original criticism upon this point will stand until Dr. Waterman or some one else does produce the crystals referred to under the circumstances indicated.

An incorrect quotation from Preyer, in the next paragraph of Dr. W.'s reply, would convey the idea that Preyer places the substance commonly called hematin among the blood-crystals, which is not a fact, Preyer stating at page 196 of the same book, that it is an amorphous substance. "Bis jetzt wurde es stets nur als Zersetzungsproduct des Bluts farb-stoffs und zwar nur in amorphen Zustände erhalten."

In subsequent paragraphs Dr. Waterman intimates that I denied the production of *any* crystals from old blood. He will nowhere find in my criticism grounds for such intimation, as I have frequently obtained crystals of hemin from old or dried blood, and certainly as much as ten years ago for microscopical examination.

HENRY G. PIFFARD, M.D.

ICHTHYOSIS OF THE TONGUE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The report of the meeting of the 21st ultimo of the Academy of Medicine, published in the RECORD, January 30, at which Dr. R. F. Weir read an excellent paper on Ichthyosis of the Tongue, I find it stated that Dr. R. W. Taylor joined in the discussion. Owing to severe hoarseness I perhaps was not heard by all present and I should not have spoken, but at the request of the President, as the subject under discussion is somewhat new in this country, at least to its literature, and as all contributions are of some value, I desire to state in your columns what I said there, offering the observations in a suggestive manner. Dr. Weir went very carefully over the clinical features of a large number of cases and from these, as well as from personal observation of several cases, I think we are warranted in stating the fact that there are two distinct morbid processes involved in the lesion which is now following Hulke, called ichthyosis of the tongue. In one class there is to be noticed a localized warty and thickened condition of the mucous membrane, it being very evident that the thickening involves all of the dermal structures. In the second variety there is an absence of the warty appearance and a very perceptible thickening of the epithelial layer. In this variety the lesion is of greater extent and may involve the whole dorsum of the tongue, encroaching on its under surface and sometimes also being found on the inner side of the cheeks. The affection also may be limited to patches. In any condition the color of the thickened membrane is of a bluish or pearly white, sometimes of a dirty brownish-white; this latter appearance being usually seen towards the median line. Reasoning by analogy from known facts as to the primary origin of certain morbid processes in certain portions of the skin, it has occurred to me that the lesion of the first form of disease described is in the papillæ primarily and that the other structures are secondarily involved, the whole constituting the warty appearances which are alluded to. Now in the second variety I am of the opinion that the lesion begins in the rete Malpighii, from which it is

thought that the epithelial cells are developed. Owing to hyperplasia of these elements, the thickening is produced, which is, as I have said, either general or local. Though the proliferative process in the rete may be of long duration, it will be observed that the other structures of the membrane do not undergo corresponding increase, consequently we have the flat patches. I am inclined to think that in this variety the papillæ are not markedly prone to enlargement. This point was well shown by a case which I observed, and included by Dr. W. in his paper. In this, together with great epithelial thickening, there was much increase and condensation of the sub-mucous connective tissue, yet the papillæ were not prominent. In some cases, however, it will be seen that the papillæ are moderately enlarged, but that they are not of the warty appearance of the first variety. I am inclined to think, therefore, that we include under ichthyosis of the tongue two forms of lesion, the one a variety of papilloma, the other a true keratosis. The former is the one most liable to undergo, at late periods, epithelial carcinomatous degeneration, whereas the other has no malignant sequelæ. As the etiology of these affections is carefully considered by Dr. Weir, in his paper, I leave the subject undiscussed here.

Respectfully,

R. W. TAYLOR, M.D.

125 E. 12TH STREET, Jan. 30, 1875.

METASTASIS OF PAROTITIS TO THE BRAIN.

TO THE EDITOR OF THE NEW YORK MEDICAL RECORD.

SIR:—In THE RECORD for Jan. 9 there is a case, reported by Dr. Kemp, of parotitis, terminating fatally by metastasis to the brain. He observes that it is the only instance reported of which he is cognizant, with the exception of one occurring in the experience of Dr. Dickson, of Charleston.

To add to the literature of this uncommon complication I would mention two cases, which came under my observation while a student of medicine in Washington, D.C. They occurred in the practice of Dr. W. P. Johnston, a leading practitioner of that city. One of the cases was a fellow medical student, aged twenty. The other was his brother, two years younger. The eldest was taken ill first, and in a few days metastasis to the brain occurred, which terminated fatally in four days. About a week later the brother was attacked and succumbed from the same complication.

I am not aware that these cases have ever been placed on record, but they have been related by me at several of the medical societies, while a resident of New York.

E. LEE JONES, M.D.

OAKLAND, CALIFORNIA, January 18, 1875.

Other cases of this disease will be found mentioned in an article by Dr. Radcliffe, published in the *Philad. Medical Times* for Aug. 15, 1874, an extract of which appeared in THE MEDICAL RECORD for 1874, p. 514.—Ed.

MEDICAL LEGISLATION IN NEW JERSEY.—On the 30th of January, a bill was introduced in the New Jersey Legislature, providing for the establishment of a Board of Health, to consist of ten persons, to be appointed by the Governor, who shall act without remuneration, shall investigate the causes of all diseases among men and animals, and report annually to the Governor.

Obituary.

EDWARD DELAFIELD, M.D., LL.D.

DR. EDWARD DELAFIELD died at his residence in this city, on Saturday the 13th inst., aged eighty-one. He was born in New York, May 17, 1794, and was one of eleven children—seven sons and four daughters, all of whom attained more than average distinction in professional or social life. His father, John Delafield, accounted one of our wealthiest old-time residents, came originally from London, England, and was united in marriage to Miss Ann Hallett, a native of this city.

A pupil in several of the best schools of the day, he eventually graduated from Yale College, New Haven, in 1812, and four years afterwards obtained his medical degree from the College of Physicians and Surgeons, N. Y. A year's sojourn in Europe, during which he visited the London and Parisian hospitals, prepared him for his entrance upon professional life, and the prosecution of a most useful career. Always progressive, he soon conceived the idea of an institution for the exclusive treatment of eye diseases, and in connection with the late Dr. J. Kearney Rodgers, founded the New York Eye Infirmary, which was duly organized April 21, 1821, under the presidency of William Few, Esq.

Soon after the foundation of the infirmary he became a partner of Dr. Borrowe, and was early introduced into a large practice. In 1834 he was appointed one of the attending physicians to the New York Hospital, a position which he held for four years. In 1825 he was appointed Professor of Obstetrics and Diseases of Women and Children in the College of Physicians and Surgeons, and continued to fill the chair with signal ability until the year 1838, when his increasing private practice obliged him reluctantly to resign both his professorship at the college and his position at the hospital. In the year 1842 he became the founder of the Society for the Relief of the Widows and Orphans of Medical Men, of which he was the first President, and to the management of whose affairs he always devoted much of his time. In 1858 he was elected President of the College of Physicians and Surgeons, a position which he held at the time of his death. As President of the college he became a member of the Board of Governors of the Roosevelt Hospital, of which board he was the President. He was Chairman of the Building Committee of the hospital, and devoted himself unsparingly to the details of the building and the organization of the institution. As a teacher Dr. Delafield was quiet, clear, methodical, emphatic in his views, terse, elegant, and distinct in his mode of expressing them. In the esteem of the profession of this city as a man of enlarged views, and benevolent impulses, Dr. Delafield held a distinguished place. He was ever the wise counsellor, the enthusiastic patron of merit, and the public spirited citizen. A popular practitioner among the wealthy classes his success was no less deserving than decided. Many of his old pupils still survive to venerate his memory—and legions of friends, tried and true, will pay the tribute of a tear to his sterling worth.

DR. E. S. DUNSTER is reported to have resigned the Professorship of Obstetrics in the Long Island College Hospital.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from February 1st to February 13th, 1875.

ROSE, GEO. S., Assistant Surgeon.—Granted leave of absence for one month. S. O. 24, A. G. O., Feb. 8, 1875.

Medical Items and News.

SCHOOL HYGIENE IN RHODE ISLAND.—Last year the State Medical Society of Rhode Island referred to a Committee the subject of "School Hygiene," with instructions to investigate and report thereon. The report has recently been presented to the Society, which, after earnest consideration, unanimously passed the following resolutions:

Resolved, That physical culture is of primary importance in our public schools, and that gymnastic exercise should be made a part of our school system; that the "Kindergarten system" should be engrafted upon our public school system; that the school buildings should not exceed two stories in height; that 300 cubic feet of space and 25 square feet of floor space should be the minimum for each child in a school-room in connection with good ventilation; that proper warmth and pure air are of the first importance, and should always be considered before ornamentation; that scholars should not maintain the same position more than half an hour at a time; that two short sessions, daily, are better than one long one; that no child should be admitted into our public schools as now conducted, under seven years of age; that under twelve years of age, three hours a day, and for twelve years and over, four hours a day, is sufficiently long confinement to mental culture; that study out of school should not usually be permitted; that all incentives to emulation should be used cautiously, especially with girls; that the "half-time system" should be introduced into our public schools.

THE SUFFOLK DISTRICT Medical Society of Massachusetts, at its last meeting, concluded that it was *expedient* to send delegates to the next meeting of the American Medical Association.

THE INSANE DEPARTMENT OF THE PHILADELPHIA ALMS HOUSE, with accommodations for five hundred inmates, is said to actually contain one thousand and five, and has been declared by the Grand Jury to be a disgrace to the city.

OPHTHALMIC AND AURAL INSTITUTE.—At the annual election of Trustees of the New York Ophthalmic and Aural Institute, the following were chosen to serve three years: W. T. Blodgett, Dr. Knapp, Jesse Seligman, W. C. Langley, Dr. Linsley, Andrew J. Norwood, and James R. Paddock.

RECONSTRUCTION OF SURGICAL STAFF OF POLICE DEPARTMENT.—The Board of Police Commissioners has abolished the Board of Examining Surgeons and appointed the same on the general staff. The re-districting of the city was another change made. Each one of the nineteen surgeons is assigned to the police district in which he resides. A committee of three surgeons, appointed in rotation, are to attend on Tuesday of each week to examine applicants for admission into the police force. The President of the Surgical Board reports daily at headquarters. The new appointments of police surgeons are Drs. K. F. MacLennan, W. A. Varian and F. M. Purroy. The salary is fixed at \$1,500 per annum, a ridiculously small compensation for the services required.

ALUMNI PRIZE.—At a recent meeting of the Council of the Alumni Association of the Bellevue Hospital Med. Col., it was voted that an annual prize be established for the best thesis submitted by an alumnus. The contesting papers are to be in the hands of the President of the Association before January 1st, of each year, and are to be accompanied with a sealed and marked envelope containing the name of the writer; the thesis bearing a mark corresponding to the one on the envelope. The decision of the judges will be declared at the time of the annual graduating exercises of the school.

M. CHEVREUL, the eminent French chemist, who is now eighty-eight years of age, has been promoted by Marshal MacMahon to the dignity of Grand Cross of the Legion of Honor, in recognition of his services to science.

UNIVERSITY MEDICAL COLLEGE.—The Thirty-Fourth Annual Commencement of the Medical Department, University of the City of New York, was held at Steinway Hall, Tuesday evening, February 16th, at 8 o'clock. After the reading of the Scriptures and prayer, by Chancellor Crosby, the degree of M.D. was conferred upon the graduating class. The Valedictory Address to graduates was delivered by Rev. Wm. M. Taylor, D.D.; also a Valedictory Address by F. W. Spaulding, A.B., of the Graduating Class. The following prizes were then awarded:

The Mott Prizes.—The Gold Medal to Alexander Dallas, N. Y.; the Silver Medal to George A. Balcom, Nova Scotia; the Bronze Medal to Franz Heuel, N. Y. Prof. Budd's Prize, for the best examination in Obstetrics, to Charles S. Webb, of Va.; Prof. Loomis' Prize, for the best examination in Pathology and Practical Medicine, to R. J. Heinmüller, of N. Y.; Prof. Thomson's Prize, for the best examination on *Materia Medica* and Therapeutics, to Frank L. Smith, of Mass.; Prof. Roosa's Prize, for the best examination on Diseases of the Eye and Ear, to K. Kekimian Sewny, of Turkey; Prof. Arnold's Prize, for the best examination on Physiology, to K. H. Sewny, of Turkey; Prof. Elsberg's Prize, for the best examination in Laryngology and Diseases of the Throat, to Alexander Dallas, of N. Y.; Dr. Pallen's Prize, for the best examination in the Surgical Diseases of Women, to J. E. Paine, of Miss.; Prof. Piffard's Prize, for the best record of his lectures, to Alexander Dallas, N. Y.; the James Bryce Prize of fifty dollars, for the best Thesis on a subject relating to Obstetric Medicine, to Henry Furness, of N. Y. Honorable mention was made of Theses written for the Bryce Prize by James L. Nicholson and G. R. Moloney; Prof. Gillette's Prize, for the best record of lectures on Obstetrics, to Franz Heuel, of N. Y.; Dr. Ranney's Prize, for the best record of his lectures, to Anthony Peck, Jr.

A CASE OF INTERMITTENT CHYLURIA.—The following rare case is reported by Elme. A carriage driver, fifty years of age, was in the habit of passing an intensely white urine every night between the hour of midnight and five or six o'clock in the morning. The urine proved on examination to be chylous, *i. e.*, it contained fat and albumen. The urine passed during the day was perfectly normal. This peculiarity of the night urine was first observed by the patient about the end of the year 1872, and it only disappeared about seven weeks before his death, which occurred early in 1874, from carcinoma of the pylorus, as shown by post-mortem examination. The patient had never lived in the tropics, which was regarded as remarkable,

because the disease is usually connected with a longer or shorter stay in those parts.—*Deutch. Arch. f. klin. Med., Berl. klin. Woch.,* 48, 1874.

REPORT OF THE HEALTH OFFICER OF THE CITY AND COUNTY OF SAN FRANCISCO, for the fiscal year, ending June 30, 1874. Henry Gibbons, Jr., M.D., Health Officer.—According to Dr. Gibbons's report, there were 4,013 deaths from all causes, the mortality of the year preceding being 3,641. A large proportion of this increase was due to an epidemic of scarlatina, but for which the mortality would have been smaller than in 1873. The population of San Francisco, according to the estimate made in the City Directory, is about 200,770, which gives a mortality rate of about two per cent. of the population. If, however, the Chinese are excluded from the calculation (their number being estimated at 14,500) the result is somewhat different. While twenty per thousand of the total population died, the rate among the whites was but nineteen, while among the Chinese it reached thirty-two, or more than half as much again. This difference is rendered more remarkable by a comparison of the mortality rates of adult whites and Chinese—a juster base of comparison, since Chinese children are in such small minority. This comparison shows either that the death-rate among Chinese is twice as great as among whites, or the estimates of their numbers are far too low.

INDEPENDENT JOURNALISM.—Dr. E. S. Gaillard, the editor of the *American Medical Weekly*, in speaking of the rights of independent journalism in America, says:—"So long as medical journals are ruled and controlled by wealthy publishing houses, who use them for mercantile and commercial purposes; for stimulating trade; swelling profits on book sales; who employ editors to use 'the scissors' and play the rôle of proof-reader only; refusing to them the manifest right of independent, though dangerous and pecuniarily unprofitable criticism; so long will such journals be only the repositories of extracted and original medical papers; so long will they fail to do anything beyond this for a profession which needs every support to maintain, in this country, the position which is generally and justly accorded to it elsewhere." We believe in the doctrine, and have on more than one occasion been compelled to contend for its maintenance. Dr. Gaillard has a right to preach as he does because he practises accordingly.

GOOD ADVICE TO A DYSPEPTIC.—The *Boston Jour. of Chemistry* says: "A gentleman saw an advertisement that a recipe for the cure of dyspepsia might be had by sending two postage stamps to the advertiser, and the answer was, dig in your garden and let whiskey alone."

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, Feb. 22.—Medical Society of the County of New York.

Tuesday, Feb. 23.—American Microscopic Society. Yorkville Medical Society.

Wednesday, Feb. 24.—New York Pathological Society.

Thursday, Feb. 25.—New York Medico-Legal Society. Brooklyn Pathological Society. Jersey City Pathological Society.

Friday, Feb. 26.—Medical Library and Journal Association, "Report on Physiology." Dr. Geo. B. Fowler.

Saturday, Feb. 27.—New York Medical and Surgical Society.

Medical Department of Life Insurance.

THE PROFIT TO LIFE INSURANCE COMPANIES

IN

PROMOTING PUBLIC HEALTH MEASURES.

By J. R. BLACK, M.D.,

NEWARK, OHIO.

THE recent meeting of the American Public Health Association in Philadelphia was made up almost exclusively of well-matured, gray-headed medical men. The inquiry very naturally arises, what interest can medical men have in the preservation of health when the largeness of their income depends upon its destruction? Do lawyers in a representative body ever meet to devise means to lessen crime, or do they publish a single journal for the purpose of elucidating the methods by which much litigation may be avoided? All know that they do nothing of the kind, yet in their ranks are many noble lovers of their race, men who do not hesitate to make sacrifice of their interests *pro bono publico*. The difference can only be accounted for by the character of the respective occupations. That of the lawyer has its mainspring in the excesses of human passions and in the waywardness of poorly-balanced minds. The questions chiefly involved are, whether any one has voluntarily forfeited his right to life, liberty or the possession of property. In preventing or removing the causes of unlawful acts, the lawyer cannot feel that he knows more, or that he can do more, than any one else. On the other hand, the occupation of the physician has very little dependence upon mental temperament; it arises from erroneous conceptions in reference to individual responsibility in disease, and of the manner in which mankind should use themselves, or from the changes which they misguidedly effect in their external relations. Moreover, the prevalence of disease involves unspeakable suffering, long-continued misery, privations and premature death. The physician sees and realizes these things more clearly and deeply than any one else, and, besides, to what a great extent knowledge and systematic organized effort would remove them all. The more the physician sees of disease, the longer his experience in contending against it, the more is his heart stirred within him at the wide-prevailing misery and unnecessary destruction of life which springs from the sway of ignorance and of short-sighted folly. His perceptions being clearer and more profoundly excited by a constant insight into the extent and intensity of human misery arising from avoidable diseases than can happen to the followers of any other occupation, he is moved to enlighten his fellow-beings upon the subject, even if it strikes at the very source which renders his professional services a necessity. The evidence to him of the immeasurable benefits which would accrue from a thorough enlightenment of the public mind upon the means through and extent to which health may be preserved is so overwhelming as to produce absolute and enthusiastic conviction. It is from considerations like these that nearly every physician of liberal culture and genuine philanthropy becomes in his riper years an enthusiast—or as some say, almost a monomaniac—on the subject of hygiene.

It is no longer necessary to adduce evidence to prove that the average duration of human life has, within the past two centuries, been greatly extended. The fact is fully established, and well known to all

who have given the subject of vital statistics any attention. But the minds of very few are clear as to the precise means through which this extension has been effected. Is there any reason for supposing that this decreased ratio of mortality is the result of spontaneous changes in natural or in supernatural influences? Not a tittle of evidence has been produced, or for that matter can be produced, to prove anything of the kind; and if these be excluded the only remaining source of a change in the influences or relations which affect health and the duration of life is in man himself. That, as a voluntary agent, he has produced very great changes for the better in the modes of using himself as well as in his environment, and to these are due the improvement of his health and longevity, is established as far as the sequence of events is capable of establishing a uniformity of relation. In other words, the relation and sequence of acts and events have clearly shown that to the care of man is entrusted his own physical weal or woe, and whether his life shall be sickly and short, or whether it shall be healthy and prolonged to the greatest natural limit.

The history of hygiene very clearly shows that improvements have been wrought in man's external and internal condition—and in what these improvements mainly consist. In part, they have been of a private, but more largely of a public nature. A larger and better supply of food, cheaper and better clothing, greater care in household ventilation and cleanliness; and, on the whole, more sober and temperate modes of living have contributed not a little to the improved longevity; but in the past, as in the present, the most destructive influences to health and life have arisen from the conditions that attend the dense aggregation of human beings in towns and cities; such as overcrowding, filth, destitution, bad air, impure water, etc. These with some others unite in producing a depravity in the vital fluids exceedingly favorable to the development of disease—even from the natural variations of the elements—but more especially through this dense aggregation to the spread of infectious and contagious diseases, in their nature often extremely destructive to life.

Much has been done during the last four centuries to remove some of the conditions so inimical to life in towns and cities, and with the effect, as in Geneva, of doubling the expectation of life in two centuries, and of diminishing the death-rate in London from 50 in the sixteenth century to 22 in the present.

It remains to inquire if all is done that can be in this direction, and if the average longevity has attained the highest figure which it is reasonable to suppose it capable of. Certainly no one at all versed in sanitary knowledge would give an affirmative answer to the first inquiry; for not only is there the grossest ignorance of the fundamental principles of hygiene commonly displayed in State and Municipal regulations, when the true principle could have been carried out quite as easily and economically, and sometimes more so than the false one—but the progress of sanitary science itself has of late displayed possibilities in extinguishing disease of which our ancestors had no conception, and concerning which the mass of the laity today are very little, if at all, informed. Consequently, the second inquiry will be answered by those familiar with the march of knowledge, that we are yet scarcely beyond the threshold of the advance in longevity to which it is possible for our race to attain.

Granting all this to be true, and I feel assured that no sanitarian will differ from me, by what means are further advances to be made, and upon whom should

the labor of its achievement chiefly devolve? The efforts of a sanitarian here and there may do something to infuse a little information on these topics among the masses, but his efforts are likely to be desultory, the impressions he makes to be transitory, or it may be altogether set aside by the dictum of some charlatan.

In the promotion of scientific knowledge there is usually developed two distinct classes of laborers; the discoverers, or those who pursue science for its own sake; and the appliers, or those who seek to make the knowledge it confers useful, and so turn it into a source of profit to themselves and of advantage to the public. The history of electricity strikingly displays these distinct pursuits. Volta, Franklin, Arago and Faraday were the leading discoverers, Morse and Wheatstone the leading appliers. Were it not for the latter the progress of science would be practically useless—or it would be like an ingenious piece of mechanism of which no one had any knowledge, serving the purpose of curious speculation, but not of a wise utility.

Another characteristic phase of modern progress is the great extent to which the division of pursuits has been carried, and the high degree of excellence to which they have attained; involving the exclusive application of a lifetime in order to attain the highest order of skill in products or results. The investigations of men who have made the subject of hygiene a specialty have of late added greatly to the facts and deductions pertaining to sanitation; but in our country, save to a very limited extent, it has not reached the rank of an applied science. There are not, as in applied electricity, a class of skilled experts to make public the benefits it is capable of conferring; in fact, in a popular or public sense, in nearly all the States it may be said to be a dead or an unrecognized science. From the very nature of public sanitation, its benefits cannot be made practical except through legal enactments. In all densely populated sections are involved certain physical relations of one person to another, of corporate authorities to the public, and the general and particular states of the environments to which communities give rise. When families are closely aggregated, as in towns and cities, the ignorance or carelessness of one may and often does, not only destroy the health of others, but oftentimes life itself. This may arise from an unnecessary pollution of the air which innocent persons have to respire with noxious or infectious substances, or it may arise from overcrowding in tenement-houses, whereby extreme violence is given to some contagious disease by which the health of an entire neighborhood is imperilled, and many lives destroyed. Like results may and often do ensue to the public from the ignorance or carelessness of municipal authorities. They may, through the quality of water furnished, cause the production or propagation of a vast amount of disease and death; or they may, through a vicious system of sewers and drainage, become the responsible agents for the widespread prevalence of some destructive disease, such as typhoid fever and cholera.

Every town or city gives origin to a peculiar hygienic environment, in which is bound up to a greater or less degree the physical welfare of the inhabitants. There are, in such places, so many sources by which the air may be contaminated, local supplies of water polluted, and the spread of infectious diseases facilitated, that the utmost care of one does not secure immunity from the consequences which ensue from the ignorance or carelessness of others. Hence, in this as in the other examples, it is but carrying out the first law of our nature—that of self-preservation—when

we ask that the law render us due protection against the ignorance or folly of others, which we as individuals are unable to secure for ourselves. And, to do this effectually, it is first of all requisite that the science of public health shall be administered by those who are experts in this kind of knowledge, just as the sciences of law and medicine are so administered. In no other way is it possible or practicable to apply sanitary science for the general good, and so put an end by public means to the existing wastefulness of health and life.

In carrying out such an object, it is of course necessary that each State shall organize a department of public health and put a competent officer at its head—assisted by other officers of a like character in all the larger towns and cities. The effect of such a course in improving the chances of life would be immediate and systematic. Blunders of the most serious character by municipal authorities would be prevented by the thousand; the causes of endemics and epidemics would be closely studied and more successfully combated; the contagium of infectious diseases localized or destroyed; in short, the whole subject of disease prevention would be invested with a new interest and placed on surer grounds of success.

As an illustration of what might be effected in a single case by organized authority in the suppression of disease, let us suppose that each State was provided with a properly empowered Commissioner of Health, who would issue to the health officers of all towns and cities the following instructions: Long-continued and careful observation having conclusively shown that typhoid fever is not a contagious disease—or directly communicable from person to person, but that it spreads and spreads chiefly, if not exclusively, from the exertions of those affected by it (see Budd, Sanderson, Murchison and Liebermeister), it will be the duty of physicians to promptly report every case of such disease to health officers, who will see that all typhoid dejections are immediately disinfected and buried; soiled linen from the same source to be disinfected, and articles like straw which cannot be so treated to be burned. The effect of a general, thorough and systematic enforcement of such instructions would be that typhoid fever would become a very rare disease, and that deaths from it would be reduced to a very small if not a fractional percentage.

It is almost needless to say that in no State, unless quite recently, has anything of this kind been systematically attempted; but, on the contrary, the very means are habitually used which should be, if it were desired to keep the disease alive by a constant succession of fresh victims; *i. e.*, not to disinfect typhoid excretions, and then throw them into vaults or sewers, or upon the open ground—where the contagium can undergo the metamorphosis necessary to infect new victims, and destroy lives by the thousand every year.

The extreme laxity and indifference in reference to the means through which the extension of disease might be limited and many lives saved is well illustrated by the fact that, so far as I am aware, no general or State law prohibits those sick of an acute contagious disease from going where they will; or which defines when those who have recently been so shall be free from all restraint, so far as travelling upon the highways is concerned. I have known persons in the desquamative stage of small-pox and scarlet fever to appear on the streets, to travel on the highways, and occupy beds in our public-houses, and no law to say them nay. Under an enlightened sanitary code this could not be; the public health, and with it life, should be protected quite as much against such a

source of insidious danger to life, as against the more open attacks of the assassin.

The efficiency of preventive measures against some of the most deadly epidemic diseases has been repeatedly and conclusively demonstrated. Pettenkofer, Harris, Budd and others have shown that Asiatic cholera when introduced into a city can be stamped out, at least to such an extent as to prevent it assuming the proportions of an epidemic. The protection which thorough hygienic measures are capable of affording against the prevalence of yellow fever has never been more conclusively demonstrated than during the occupation of New Orleans by the Union army for three years in the late war; such a thorough execution of sanitary measures in New Orleans had never before been seen, neither had such an exemption from yellow fever been ever known to occur in the history of that place; and this, too, in the face of the fact that over 100,000 unacclimated soldiers were either stationed or passed through the city during the period named.

These are a few of the grounds upon which sanitarians base their conviction that, when hygiene becomes a publicly recognized and practical science, it will be able to effect a much greater prolongation of life in the future than it has in the past. This prolongation will not of necessity be rapid, but it will be sure; exhibiting a steady rise in the average. But if such a beneficent result is to be speedily inaugurated, something more than the isolated efforts of philanthropic physicians must be brought to bear in the great and good work. The public are suspicious of those who profess to act from motives of pure philanthropy, even although no other is apparent. The masses are very apt to look upon professions of this kind as the movement of a class who must have some selfish end in view. But the interests of physicians happen to be nearly all on the other side—they can have no motive in promoting the public health aside from the love they have for the welfare of their kind—and it may be, the occasional occupancy by one of their number of a position of trust in directing the reformatory movement. So far, they have been almost the sole class who have done anything to promote the public health, and from the cause just assigned, what has been done is very far from what ought to have been; while the gap between private knowledge and public practices is being increased almost every day by the rapid strides which sanitarians are making in the perfecting of this science. In looking around for coadjutors, or for those whose presumed desire to aid a good cause would be ripened into instant resolve by the potent influence of an increase in the profits of their occupation, the mind instantly attaches itself to those engaged in the business of life insurance. This class of all others would have their interests largely advanced by a gradual rise in the average of longevity. Basing their calculations upon a certain average of life to their rates of insurance, if there was a gradual sinking of this average below the standard, the effect would in the long run be exceedingly disastrous to their interests; but, on the other hand, if there was a gradual rise of the average above the standard the effect would be an ever growing prosperity and enlargement of their resources. True, a rectification of the basis upon which life insurance companies determine their rates would become from time to time necessary; yet if the average expectation of life had a constant tendency to grow beyond each new adjustment, as constant a tendency to a progressive augmentation of their profits would necessarily ensue.

The advantages which would accrue to these engaged in life insurance by a steady rise in the expectation of

life are so obvious that it is needless to dwell upon the matter. The only points upon which there may be doubt, to those not very familiar with the progress of sanitary science, are whether such an augmentation in the average of life is practical, and if so, by what means can the augmentation be most speedily and securely effected?

* I have already shown that the experience of the past has amply demonstrated its practicability. I hazard nothing in saying that there is not a single physician or sanitarian thoroughly versed in the etiology of disease who will not avow that, so far from having reached the limits of the practical in health and longevity, we are just well over the threshold. We are yet as a people scarcely over that dread and superstition of the middle ages which led all to regard a pestilential epidemic as an infliction sent for some form of spiritual wickedness, and hence to be met by sacrifices, votive offerings and intercessions addressed to the gods. It is only about two hundred and fifty years since the first attempt was made at Marseilles to stay the progress of the plague by what was understood as profane but what are now called sanitary measures. In fact, in this department of knowledge the student is able to discover the analogues of the three stages which some writers have portrayed in the growth of civilization and of religion. In civilization the three eras are represented by typical forms of handiwork—as in the age of stone, the age of bronze, and the age of iron; in the growth of religious sentiment, by typical ideas, as in the age of superstition, the age of faith, and the age of reason. Similarly in the history of medicine there are three distinct stages of growth in reference to the conceptions of the causes of disease; the supernatural, or that in which diseases were attributed to the anger of the gods or to the influence of evil spirits; the natural, or that in which nature or her processes were supposed to be at war with man's physical welfare; and third, the human, or that in which man is himself regarded as the responsible agent for the existence of his diseases. The shadow of the first yet overhangs the popular mind, and that of the second over the followers of Hippocrates. A natural outcome of this development of ideas upon the sources of disease was, for the first, interceding or exorcising priests; for the second, the physician; and, for the third, the sanitarian. The notion that a priest may stay the progress of a pestilence by prayers or incantations is now held only by savages, and the opinion yet entertained by some physicians that nature in her operations is more inimical to man's healthy existence than to any other animated being, for he is indisputably the most sickly, is gradually being superseded by that of human responsibility. Why nature should be deemed more at enmity with the human than with any other kind of organism is not very easy to divine; besides, the increase in the average duration of life during the past three hundred years is wholly inexplicable on any other than the hypothesis of personal causation. The processes of nature are precisely what they were three centuries ago, but one of their assumed effects, the physical diseases of man, has undergone a very great change for the better. In that time nearly all the more terrible pestilences have disappeared, and those that remain are very much milder and less frequent in their appearance; so that unless variability can be shown in the course of nature, variability in one of the assumed consequents, disease cannot be attributed to invariability of the antecedent.

That human exemption from disease and an extension of the term of life have a uniform relation to the degree of observance which is rendered to the condi-

tions of health has been established by a multitude of facts, and to this, and this alone, except in the solitary instance of the practice of vaccination as a guard against small-pox, is due the degree of exemption which is displayed from the one, and the degree of extension which is enjoyed of the other.

The life insurance interest can aid sanitary reform in a very effectual manner by giving substantial support to associations and publications devoted to the promotion of the public health, and by fostering the organization of State and National sanitary departments, in order that this branch of knowledge may be practically and efficiently administered by its experts, and at the same time through the diffusion of information arouse and quicken a popular interest on the subject.

It should be borne in mind that the factors of success are very different in public from what they are in private hygiene. The realization of the benefits of private depend first on individual knowledge of what to do, and second on the will to do it. There are of course very few who possess both requisites, many acting ignorantly in some things and willfully in others. In public hygiene, under a thorough and enlightened sanitary code, a few men are selected on account of their exceptional fitness in a knowledge of how and what to do, to administer the provisions of the law. The subject of public health is their specialty, they know it more thoroughly than they do any other department of learning, and hence are capable and able to give the public the entire benefit of their exceptional knowledge. The greatest obstacle to the successful application of private hygiene, that of rendering every person equal to an expert, is obviated in the public, and there is therefore no adequate cause to hinder the people of each State from immediately reaping all the advantages to their health which the most advanced public sanitation of the world is capable of affording. Though a few States have recently organized departments of public health, yet the work of reformation has scarcely more than made a beginning, and its promoters are not yet provided with an efficient code by which systematic work can be effected. Here is a wide field in which the life insurance interest can aid in a philanthropic work, and at the same time enhance the prosperity of its organizations.

It is only through such departments that vital statistics can be properly collected, and made to tell the tale in a manner that all can understand of local mismanagement, or of an undue prevalence and mortality from the avoidable causes of disease; to reveal in many instances what those causes are, to exhibit the success of the measures adopted for their removal, and to impress upon local authorities and the public at large a sense of responsibility for the existence of preventible maladies in their midst. Through such organizations only can systematic measures be taken for limiting the spread, and for stamping out the germs of infectious and contagious diseases, and in the event of any pestilential epidemic threatening our shores to take concerted action to prevent its ingress or to limit its ravages.

By the adoption of such measures only can experts in sanitary science be brought to the foreground of action, and furnish to local authorities the most approved methods for the disposal of, and the best conduits for sewage, to advise upon the best means of ventilation for public buildings, to investigate the origin and causes of severe local endemics or epidemics, and advise in reference to the best means of their removal, to inquire into the quality of public

water supplies, to guard against the purchase of poisonous commodities such as arsenical paper hangings, toys, etc.; to order chemical or microscopical investigations of suspected unwholesomeness or adulterations in foods or drinks; in a word, to stand as a skilful and alert watchman on the tower to guard and warn against those insidious enemies which steal into our lungs and blood, and destroy both health and life.

THE DISEASES CAUSED

BY THE

INHALATION OF THOSE KINDS OF DUST WHOSE PRESENCE IN THE PULMONARY TISSUE MAY BE DEMONSTRATED.

[CONTINUED FROM NO. 216, PAGE 663.]

THE DEPOSITION OF METALLIC DUST IN THE LUNGS.

Siderosis Pulmonum.

CHEMICAL tests enable us to detect the presence of metallic dust in the lungs with much greater certainty than is possible with the forms of dust which we have just considered. But, nevertheless, the study of siderosis pulmonum is a comparatively new one, and was only commenced after the existence of a disease depending upon the deposition of coal dust in the pulmonary tissue had been fully established. Moreover, the study of siderosis has thus far been limited almost entirely to the consideration of but a single metal, viz., iron. Excepting one case in a copper miner, published by Greenhow, in every instance of the disease yet reported, the affection was due to the inhalation of some form of iron dust. This circumstance is doubtless the result of the more frequent employment of iron than of the other metals.

What was said under anthracosis with regard to the fineness of the dust, its density and the insufficiency of ventilation, etc., increasing the liability to disease, applies with equal force to siderosis. But, as a rule, there is less dust produced in the manufacture and elaboration of iron than in the various coal works, for the reason that the particles are usually of a greater size and of greater weight, and so fall more readily to the ground. Still the manufacture of iron and its use in the arts are so vast in extent, and employ such a host of laborers throughout the world, that it is quite possible that siderosis may be scarcely less common than the disease produced by the inhalation of coal dust.

The first case of disease due to the inhalation of iron dust was described by Zenker in 1865. The person had been employed to color paper, by rubbing it with the dry peroxide of iron. The lungs were found colored red from inhalation of the dust. After the "red iron lung" had been described it was not long before *black iron lungs* were discovered in cases where the black oxide or the phosphate of iron had been inhaled. Finally, a fourth variety has been described, where the dust consisted of a mixture of iron and sand. In all, there have been recorded eleven cases of siderosis pulmonum depending upon the inhalation of iron dust. Of these, two were observed by Zenker, and the remaining eight by Merkel. Eight of the cases had inhaled the red oxide of iron (seven of them in paper coloring, and one was a glass-grinder), two had inhaled the black oxide in grinding sheet iron, and one the phosphate of iron in mixing colors.

These cases manifested the same catarrhal symptoms as observed in anthracosis. The particles of iron could always be demonstrated in the sputa, by adding dilute hydrochloric acid, and then the ferro cyanide of potas-

sium, when the characteristic Prussian blue appeared. The duration of the disease was exceedingly variable. In one case it lasted but nine months, though this person was not of sound health when the occupation was commenced. In another case the disease lasted for twenty-five years. The average duration after the commencement of severe symptoms—that is, such as would lead the patient to seek medical aid—was about two years. In three of the cases there was an inherited predisposition to phthisis, in three others nothing with regard to this was ascertained, and in five there was no such tendency.

The post-mortem examinations in these cases found the pulmonary tissue thickly studded with the particles of dust, though the mucous membrane of the bronchial tubes was invariably free from them. The tissue of the lung was colored red or black according to the variety of iron dust inhaled (whether the red oxide or the black magnetic), and the tissue was seen where cut to be saturated with a red or black fluid similar to that observed in the miner's lung. In inflated portions of the parenchyma a reticulated meshwork appeared with cicatricial bands inclosing the separate spaces which jut forward upon the surface of the lung. But the most characteristic and invariable feature of this form of pneumokoniosis is an appearance of hard nodules scattered through the pulmonary tissue. They vary in size from a pea to a bean, grate when cut, and on section display a grayish yellow color and a number of little spots or streaks. Many of them have a central lumen the size of a pin's head. Unless this disease has advanced to a fatal termination, but few other changes will be found. But in case the siderosis continues to progress these nodules increase in number and dimensions, and coalesce in the form of large deposits; considerable pleuritic thickenings appear, and finally cavities occur. The cavities usually still contain a few molecules of iron. Casous deposits may be also found.

Kindfleisch is of the opinion that the nodules above described are tuberculous. But Merkel denies this, and claims that even their gross appearances contradict this view. They consist of dense cicatricial connective tissue, which, on the addition of acetic acid, is seen to be beset with small, mostly spindle-shaped cells containing numerous fine, colorless (apparently fatty) granules, and some of them are quite filled with the particles of iron. He observes that he has seen miliary tubercles in siderotic lungs, but that they never contained the particles of dust observed in the nodules.

These cirrhotic nodules are regarded, in fact, as the most essential feature in the disease, and are the direct result of the irritation induced in the parenchyma of the lungs, in consequence of the presence of the particles of dust. Merkel concurs fully in the opinion of Zenker, who regards these nodules "as formations of purely irritative origin—products of chronic inflammatory processes, which have their seat in all probability in the interstitial connective tissue." "Hence," Merkel observes, "the entire process may be denominated as a lobular interstitial indurating pneumonia, which commences in the lobular bronchioles, whose walls seem to pass into a cicatricial degeneration, while the minute cavities which are found in the centre of many of the nodules probably represent the still remaining lamina."

It is very possible that in some instances deposits of iron-dust take place in the lungs without inducing any serious changes in the parenchyma. In some of those cases where in certain places cirrhotic spots were found, there were also portions which were filled with the dust, but still remained inflated.

Besides the chronic interstitial indurating processes, the ordinary pneumonic and bronchitic diseases may also occur, leading on to phthisis, with the production of cavities, as described under anthracosis.

The possibility of ascertaining the presence of iron-deposits in the lung by means of chemical tests, has been already alluded to. The following are the results of chemical examinations in five of the recorded cases of siderosis pulmonum:

(1.) Zenker's first case contained.....	1.45	per cent. Fe ² O ³
(2.) A case of Merkel's contained.....	0.97	" "
(3.) A second case of Merkel's contained.....	0.1802	" " = 0.1742 Fe ² O ⁴ .
(4.) A third case of Merkel's contained.....	0.1689	" "
(5.) A fifth case of Merkel's contained.....	0.13	" "
Dried blood contains.....	0.255	" "
The dry lung of Case 1.....	7.1	" "
The dry lung of Case 2.....	3.96	" "
The dry lung of Case 3.....	0.883	" "
The dry lung of Case 4.....	0.568	" "
The dry lung of Case 5.....	0.66	" "

It should be observed that the cases (4) and (5) were those in which the pulmonary affection did not terminate fatally.

The symptoms of siderosis pulmonum, so far as they have been observed, do not materially differ from those described in connection with the inhalation of coal-dust. The examination of the sputa will naturally yield far more satisfactory results. As a rule, the dyspnoea did not seem to be as great in this form as in anthracosis. The emphysema was not especially marked.

The duration of the disease, after the occupation necessitating the inhalation of the dust was commenced, was protracted. In three of the cases it was not ascertained, and in one instance the patient was diseased when the occupation was begun; in one case it was three years, in one four, in two seven, in one ten, in one twelve, and in one twenty-five. The phthisis which ensued in most of the cases ran its course in the usual manner, entirely uninfluenced in its general character by the dust-deposits in the lungs.

As to therapeutics it is merely suggested that the inhalation, in spray, of certain "alkaline solutions" might possibly dissolve the particles of dust so long as they remained in the alveoli or bronchioles.

Besides the form of siderosis depending upon the inhalation of iron dust, which has just been considered, attention is called, in conclusion, to two other forms of the disease. Mere mention is made of a case of pulmonary disease due to the inhalation of copper dust in a miner, described by Greenhow, which is the only instance of this variety of siderosis on record, and this is very meagrely reported. The other form spoken of is the disease known in England as the "Grinder's Asthma." In this disease the grinders are said to suffer, in some instances, from severe catarrh of the larynx and air-passages, accompanied by violent cough and profuse expectoration, with subsequent emphysema. In other cases destructive changes take place in the lungs, with all the ordinary symptoms of consumption. In the former case the progress of the disease is very slow, in the latter, usually rapid. The sputa, so it is said, frequently contains hard, stony concretions of a black color, and often as large as a small bean. Merkel gives an account of the post-mortem appearances in the lungs in a case of the disease where death was caused by an accident. Hard little nodules of the size of pin-heads were found in the tissue of the lungs, which consisted of deposits of sand and iron embedded in thickened connective tissue.

CONCERNING THE LABORERS WHO INHALE METALLIC DUST.

The laborers who obtain the iron ore from the earth are liable to the same diseases as miners generally, and the iron dust which they inhale does not appear to materially alter the character of these affections.

Blacksmiths, and the workmen employed in making knives, tools, nails, etc., are exposed to pulmonary diseases, mainly on account of the great muscular exertions which they are obliged to make, or from their exposure to intense heat, to extremes of temperature, etc., so that the dust inhaled is usually with them an element of minor importance in the production of disease. The particles of iron which are produced from the lathes and planing machines, are generally of too great size, and too heavy to take the form of dust. The machinists most exposed to the dust of iron, are the file-cutters.

The following table, prepared by Hirt, shows the percentage of various diseases, mortality, etc., in 100 patients belonging to the above class of laborers :

	Phthisis.	Chronic Bronchial Catarrh.	Emphysema.	Pneumonia.	Average duration of life.	Mortality per cent.
Blacksmiths	10.7	9.8	0.5	6.6	55.1	1.3
Nail, kn. fe, saw and tool smiths.....	12.2	12.2	3.7	3.2	37	3.3
Locksmiths	11.5	9.2	4.6	5.7	49.1	1.4
File-cutters	62	17.4	...	12.2	51.0	1.6

In the manufacture of sheet-iron it is only the men whose occupation consists in removing the incrustations of black oxide left after the hammering that are exposed to any considerable dust. The operation is performed by grinding the surface of the iron with large pieces of sand-stone dry, and the dust produced is extremely dense. One case of phthisis siderotica was observed by Merkel among these workmen.

A common source of the disease is found in the occupation of preparing the paper in which the gold-beaters lay the gold-leaf. The paper is prepared by rubbing the red peroxide of iron into it dry, during which operation the air is loaded with dust and the occupation has an exceedingly pernicious effect upon the health of those engaged in it. The same is probably true of the occupation of polishing glass by means of the red oxide, though facts with regard to this are lacking.

According to Merkel's experience cases of the disease have often resulted from the employment of mixing colors which contain phosphate of iron. The instances were observed in an establishment where railroad cars were manufactured, the colors being required for the lacquer.

Another class of laborers especially exposed to siderosis are the iron and steel grinders. They, however, inhale a mixture of iron dust and sand. English statistics show the occupation to be an exceedingly dangerous one. In Sheffield 69 per cent. of the laborers suffer from grinder's asthma, and 69 per cent. die under 40 years of age. The oldest was but 65. In Derbyshire the needle-grinders upon an average attain an age of only 33½ years, and the fork, scissors, pen, and case-knife grinders 35 years. The razor grinders occasionally live to from 40 to 50 years of age, while the scythe, saw, and file grinders, who do the grinding wet, attain a considerably greater age. In Aix-la-Chapelle, where better sanitary measures prevail, with better ventilation, etc., Hirt found a much more favorable state of things. Among 200 needle grinders

he found the mortality 2.6 per cent. a year, and the mean duration of life 50 years.

With regard to forms of siderosis pulmonum depending upon the deposition in the lungs of other kinds of metallic dust than those of iron, too few observations have been made to arrive at any positive conclusions. Next to iron the metal most likely to cause pneumokoniosis in its workers is copper, together with its alloys, brass and bronze. There are not many operations upon these metals however, where much dust is produced. It is mainly the pin-makers and workers in bronze that are exposed to dust. Especial mention is made of the operation of preparing the powdered metal for bronzing. The alloy is pounded with iron pestles in iron mortars, and the men engaged in this occupation stand in a perfect cloud of dust, looking as if they were gilded.

The following table by Hirt shows the percentage of different pulmonary diseases, in 100 patients, from this class of artisans :

	Tuberculosis.	Chronic Bronchial Catarrh.	Emphysema.	Pneumonia.	Duration of life, in years.	Mortality.
Coppersmiths	9.4	17.0	2.7	3.7	48.6	1.890
Watchmakers	26.5	19.4	2.4	4.8	55.9	2.78
Model Carvers	36.9	2.4	10.5	?	?	?
Engravers	16.3	15.7	5.2	10.5	51.6	?
Timmen	14.1	18.4	1.5	4.0	47.0	2.78
Brassfounders	31.2	9.3	15.9	?	60.1	1.594

DEPOSITION OF STONE DUST IN THE LUNGS.

Chalicosis Pulmonum.

The fact is pretty generally recognized that those who are in the habit of breathing an atmosphere that is impregnated with stone-dust are very prone to suffer from pulmonary diseases, and particularly phthisis. Peacock (in 1860) was the first to demonstrate the fact that particles of stone may become embedded in the lungs, and since him Kussmaul and Meinel have made more elaborate investigations in this direction. Meinel found 30.7 per cent. sand in the lungs of a glass-maker; 22.7 per cent. in those of a stone-cutter; and 18.2 per cent. in the lungs of a railroad station-master who was stationed in an extremely sandy region. He also found in lungs preserved as a specimen of "healed tuberculosis" in the Erlanger Pathological Institute, 45.64 per cent. of silicious earth and sand.

Chalicosis does not differ in its general course materially from those forms of pneumokoniosis which have been already described. It is said that the sputa now and then contain stony concretions. The anatomical features also resemble, in the main, those observed in siderosis. The nodules that occur in the lungs, however, are harder, and grate more under the knife when cut than in sid-rotic lungs. Moreover, they do not attain as large a size as in the iron-lung, nor become coalescent. The same bronchitic and peribronchitic processes occur together with the caseous deposits, cavities, and the final eruption of tubercles. Greenhow described similar changes in "the potter's lung," in which silicious earth and clay were found. Ross described four cases of potter's lung, in the *Dublin Quarterly Journal of Medical Science*, February, 1871.

The microscopic examination of these lungs reveals the little black crystalline molecules which are characterized by sharp angles and edges, that strongly refract the light. They are best observed by cutting out one of the nodules, and treating it with boiling

hydrochloric acid, and then examining the residue with the microscope.

In speaking of the *laborers who work in stone dust*, the following three varieties of the dust are mentioned as those most likely to cause disease when inhaled, viz., the dust from the precious stones, especially diamond dust; second, the dust of flinty earths and clay; and third, calcareous dust.

Diamond cutters, as a rule, live only from thirty-three to thirty-five years of age. It is, however, not only the diamond dust inhaled which has a pernicious effect upon their health, but they are generally exposed, while at work, to the coal-gas from the little fires they use in soldering the stones to copper rods. The cutters and grinders of other precious stones have equally unhealthful occupations.

The dust developed from the quartz used in the manufacture of glass has an extremely pernicious effect upon the health of the workmen engaged in pounding up the mineral. The great hardness of the particles, and the sharpness of their edges and points, render this kind of dust especially dangerous to the lungs. Most of the workmen die early of phthisis. The grinders of the glass are not exposed to as dense a dust. Hirt found that the average duration of life amongst the glass-grinders in Silesia, was forty-two and a half years, and that when the occupation was begun as early as at the age of fifteen scarcely any lived to thirty.

The manufacture of millstones is an almost equally dangerous occupation to the workmen employed in it. Peacock states that of the workmen engaged in a London factory 40 per cent. die of tuberculosis, and that of forty-one workmen, of whom twenty-three were not over twenty years old when the occupation was commenced, the average age at death was 24.1 years. Merkel observes that, according to his experience, this class of laborers are much addicted to excessive drinking.

As for operators engaged in porcelain factories, Hirt states that from 40 to 42 per cent. of their diseases are acute or chronic pulmonary affections. The average duration of life amongst the turners was 42.5 years. The potters show about the same proneness to lung diseases, viz., 37.6 per cent. of all diseases, of which 14.7 per cent. were phthisis. Statistics with regard to the workers in sand, the stone breakers, etc., are, as a rule, unfavorable. Lime dust may be sometimes inhaled sufficiently to cause disease, as in masons and carpenters, especially when engaged in tearing down buildings. Mention is made of the habit which lithographers sometimes have of blowing away the dust produced in engraving the stone. Where many are at work in a room, the dust is considerable. Phthisis is very common among these people.

DEPOSITION OF OTHER FORMS OF DUST IN THE LUNGS.

The *deposition of tobacco-dust in the lungs* was claimed to have been observed by Zenker, in two instances, in persons who had been employed in a tobacco factory. The lungs were atrophied, and showed, here and there, in the parenchyma and bronchial glands "peculiar brown spots, which were evidently due to the penetration of tobacco-dust into the pulmonary tissues." The coloring was most marked in parts that were most atrophied. Merkel regards this form of disease as not yet fully established, and calls attention to the bad hygienic surroundings which commonly obtain among the operatives in tobacco factories, and to their customary irregular mode of life. The dust in these factories generally causes con-

siderable irritation to the air passages at first; but the operatives soon become accustomed to it and cease to notice it. Phthisis and other pulmonary complaints are, however, very common among them. Hirt states that their average duration of life is 58.3 years, and the rate of mortality 1.312 per centum.

The *deposition of cotton-dust in the lungs* (pneumonie cottonneuse) has been described as a separate disease by Cœtsem. He states that the affection commences among the operatives in cotton factories between the thirteenth and thirtieth years of life. He distinguishes a primary stage of simple catarrh, an inflammatory stage with asthmatic dyspœa, and a distressing cough with the expectoration of white, frothy, gelatinous sputa, which look like beaten white of egg, and under the microscope show little flocculent bodies which are identical with the particles of dust floating in the atmosphere of the factory rooms. The further progress of the disease resembles consumption. Its duration is from sixteen to twenty-two months. In the parenchyma of the lungs he found, post-mortem, "a grayish-white, pulpy softening, and a hard induration of a pearl-gray color that cuts with difficulty, and on section appears homogeneous and shows a few laminae of bronchi and blood-vessels."

Merkel, from analogy with the other pneumoconioses, admits the probability of the disease, but remarks that further investigations are required. The dust developed in cotton factories is often considerable, and is apt to cause catarrhs in the operatives. Many are found to leave the occupation for this reason. The people employed in the Belgian cotton factories, live to from 47 to 50 years of age, upon an average. The rate of mortality amongst them is 35 per centum.

In conclusion, a few facts are adduced, which indicate that some of the employments in woollen factories are also rendered injurious to health on account of the dust.

Miscellaneous.

INCREASE IN THE DURATION OF LIFE.—In ancient Rome, during the period between the years 260 and 360 A. D., the average duration of life among the upper classes was thirty years. In the present century, among the same classes of people it amounts to fifty years. In the sixteenth century the mean duration of life in Geneva was 21.21 years, between 1814 and 1833 it was 40.68 years, and at the present time as many people live to seventy years of age as three hundred years ago lived to the age of forty-three. In the year 1693 the British government borrowed money, the amounts borrowed to be paid in annuities, on the basis of the mean duration of life at that time. The State Treasury made thereby a good bargain, and all parties to the transaction were satisfied. Ninety-seven years later Pitt established another tontine or annuity company based on the presumption that the mortality would remain the same as 100 years before. But in this instance it transpired that the government had made a bad bargain, since while in the first tontine 10,000 persons of either sex died under the age of twenty-eight, 100 years later only 5772 males and 6416 females died under this age. From these facts it appears that life under certain favorable influences has gained in many and probably in all its forms and manifestations, both in vigor and duration. To still further promote this tendency, it is only necessary that those conditions under which the

attainment of the desired end is possible, be made to accord with the fundamental natural laws.—*Deutsche Versicherungs-Zeitung.*

MORTALITY OF RACES.—The *Deutsche Zeitung* of New Orleans contains the following interesting notes on the mortality of the two races there, taken from statistics of Dr. Chille. The mortality of the colored population has always been decidedly in excess of that of the white population, excepting during yellow-fever epidemics, this disease chiefly affecting the whites. There is no doubt that this greater mortality existed before the war in New Orleans and other cities—certainly in Charleston, Washington, Baltimore and New York. In comparing the five years of freedom from 1866-70 with the four years of slavery from 1856-60 we find the aggregate death-rate has remained about the same. But when a comparison is drawn between the white and blacks in these periods, it appears that the mortality of the blacks has greatly increased. Thus, during the four years 1856-60 (1858, a yellow-fever year, being excluded) the colored death-rate was about 44 to the thousand, and the white 39 per thousand; while in the four years 1866-70 (excluding the yellow-fever, 1867) the colored death-rate amounted to 43 and the white to only 33 per thousand. What are the causes to which we shall ascribe this larger mortality of the colored race? The official sanitary records afford scarcely any data bearing upon this point, and therefore, are of no assistance in determining the question. Some of these causes doubtless lie in the greater ignorance and improvidence of this race, and in the fact that its mortality from small-pox, cholera, consumption, still-births and diseases of children is greater. The future of this race will depend upon the degree of its natural increase by propagation. The only reports of the Health Board which throw any light upon this matter are those for the years 1872 and 1873, since these alone give the number of deaths among children under two years of age with the two races separated. Regarding the population in 1872-3 as the same as that in 1870, we find that in the year 1872, in every thousand children, 154 white children died under 2 years of age to 298 colored, and in the year 1873, 181 white and 335 colored per thousand died under the same age. This proves conclusively, that in New Orleans the mortality among the colored children as compared with the mortality of white children is enormous.—*Deutsche Versicherungs-Zeitung.*

THE PREVENTION OF CONSUMPTION.—At the general meeting of the Lower Rhein Public Health Association, in Düsseldorf, last November, Professor Röhle delivered an address on the question: "What can public hygiene do to resist the progress of consumption?" After some preliminary remarks regarding the scope of public hygiene, and its duty implied therein of contending against this worst foe of the public health, consumption, the speaker urged the great importance of a knowledge of the causes leading to this devastating disease, for the sake of discovering by this means a way to its prevention. Now, inasmuch as we may consider that there is, in very many cases, a predisposition to phthisis, which predisposition is known as scrofula, or a general feebleness of the constitution, that is, as a lack of the power of resistance in the organism to morbid influences, we may conclude that everything which tends to remove this predisposition will, to a certain extent, prevent consumption. Again, the lungs are almost always the primary, and often the sole seat of those morbid changes by which phthisis is

characterized; and so we should seek for a prime cause of disease in pernicious influences that exist in the atmosphere with which the lungs are in continual contact and communication. All experience has taught that where these deleterious influences are increased, as is the case where many people live together in large cities, in factories, barracks, prisons, or among miners, grinders, stonecutters, etc., there is a like increase in consumption. But not only are the lungs first affected usually, but the disease begins invariably in their apices. The reason for this lies in the unfavorable situation of these parts, in the fact that in many persons the apices of the lungs are scarcely ever thoroughly inflated. This is especially apt to be the case in a sedentary mode of life, particularly in certain occupations, as in tailors, shoemakers, etc. It is also often due to maldevelopment of the chest, to weakness of those muscles whose office it is to expand the upper portions of the throat where the apices of the lungs are situated. The above-mentioned predisposition—scrofula and a feeble constitution, as well as the defective development of the chest, of which we have just spoken, are often transmitted as family traits, and, so to this extent, consumption is inheritable. In view of these various predisposing causes, though the above enumeration by no means exhausts the list, many tasks devolve upon public hygiene. With regard to the abatement of scrofula, a matter of prime importance is the provision of dry, well ventilated apartments for the people. The inmates of dwellings commit many errors in the manner in which they avail themselves of the apartments they occupy, in choosing the small rooms and those secluded from the sunlight, for the children, and for sleeping apartments, instead of using the largest and sunniest rooms for this purpose. More attention, also, should be paid to the food. Milk from badly fed or unhealthy cows may alone be the cause of disease, and, in fact, may, by itself, engender consumption. The potatoes are often of an inferior variety, grown in a poor soil and insufficiently ripe, furnishing an unhealthy kind of nutriment to the poorer classes by whom the potato is used very largely. The bread, too, often has injurious properties, on account of the flour being bad, or because insufficiently baked, or eaten while too moist and fresh. The habit of sitting in constrained positions peculiar to a sedentary life, and the insufficient inflation of the lungs demands special attention. The overcrowding of school-classes, and having too many consecutive hours of instruction, will eventually have to be remedied. Why should the school-hour be an hour of sixty minutes? Why may not ten to fifteen minutes be devoted to open-air exercises and to airing the school-room? Daily exercises in an open-air gymnasium, respiratory manœuvres and the like might easily be introduced if the effort were only made, and the matter properly supervised. So soon as the necessities of the case are once generally recognized there will be no lacking of support to carry into effect the needed improvements.—*Deutsche Versicherungs-Zeitung.*

TYPOGRAPHICAL ERRORS.—We have noticed that two or three typographical errors had crept into Dr. Wey's article, published in the Jan. 16th number of *THE RECORD.* At the bottom of the first column on page 49, the word "assisted" has been used instead of "asserted;" in the tenth line from the top of the second column of the same page the word "act" should be "art;" and, finally, on page 50, "muscular tumor" should read "muscular tremor." We trust that our readers understood, by the context, the meaning of the author.

ACTIVE AND PASSIVE MOVEMENTS IN THE TREATMENT OF PARALYSIS.

By WM. R. FISHER, M.D.,

HOBOKEN, N. J.

IN our country the use of movements and manipulations in the treatment of disease is, unfortunately, chiefly in the hands of "rubbers," "manual magnetizers," and the like, and very few physicians know anything about the methods of using them, or the effects which follow their application; for the savor of quackery is so strong about the whole subject that the majority prefer to have nothing whatever to do with it. This is to be deplored; and in the hope of doing something to correct the mistaken impressions which exist in regard to the employment of these time-honored, but now much abused, means of treatment, this paper on their application to the relief and cure of palsies has been prepared.

Without going back to antiquity, there is no lack of good authority to support the claims of these agents to a position in our list of remedies for the class of diseases to which the paper refers. Robert Bently Todd says, in reference to hemiplegia with relaxed muscles: "I know nothing which more decidedly benefits the paralyzed limbs than a regular system of exercise; active, when the patient is capable of it, passive, if otherwise."* Doctor C. B. Radcliffe, in referring to the treatment of paraplegia from myelitis, says: "The efficacy of frictions and cham-pooings appear to be indisputable. The efficacy of proper movements can only be doubted by those who are unacquainted with the results arrived at by the "movement cure," and by systematic movements of one kind or another, with or without the help of mechanical apparatus."† Doctor S. Weir Mitchell says: "The results which I have seen obtained by practised rubbers were certainly to be gained by no other equally rapid treatment."‡ J. Hughes Bennet, § Iuman, ¶ Vogel, ¶ Geo. B. Wood, ** West, †† Bouchut, ‡‡ and many others, have testified to the efficacy of movements, and recommended, more or less emphatically, their employment in the treatment of paralysis. Still they are seldom used, and a therapeutic means which has received such indorsements is left by the medical profession in the hands of quacks and charlatans.

The indications which are to be met with in treating a paralysis are threefold:

First, to maintain the nutrition of the paralyzed part, in order to prevent interstitial degeneration, atrophy and the deformities which are peculiar to paralysis.

Second, to modify the abnormal processes at the seat of the paralyzing lesion, so that repair may be there instituted; and

Third, to promote the restoration of the interrupted

relation between the nerve-centre and its peripheral distribution, for the re-establishment of function.

Active and passive movements are capable of responding, under suitable circumstances, to each of these requirements with more or less efficacy; while, in regard to the third division—the renewal of voluntary control over muscular action—the superiority of systematic active exercises over every other plan of treatment does not admit of question.

The first indication may be reached by various modifications of mechanical force, applied to the paralyzed region either by the hands of an experienced manipulator, or by some labor-saving machine. It is unnecessary to enter here upon a detailed account of the various manipulations which may be practised for this purpose; let it suffice to say that the patient is for the most part entirely *passive* during the administration of such mechanical processes as rubbing, movements of the joints, kneading of the muscles, vibrations of the limbs—in short, all the manipulations which the French group under the term *massage*. From their proper use various results may be obtained, in accordance with the especial object which is sought. The growth of the tissues of a paralyzed limb, from the skin to the bone itself, may be most advantageously modified, the temperature being increased, the circulation of the blood quickened, and the interstitial changes of nutrition rendered more complete. Hence the general comfort of the patient is decidedly promoted by these manipulations. Again, by means of passive movements the large joints, which are prone to suffer secondarily in the course of paralyzes which involve the extremities, can usually be maintained in a healthful condition. Such of the so-called paralytic deformities as depend on passive shortening of muscles, together with stiffening of the fibrous tissues about the joints, which annoy and embarrass the patient, as well as often prove a cause of actual suffering, can be prevented, or, if they have been allowed to become established, can be removed. So, too, that form of inflammation of the shoulder-joint which Chareot and Hitzig have described* as sometimes arising in the course of hemiplegia, from the continuous pressure of the joint-surfaces, finds its only treatment, for prophylaxis as well as cure, in such passive exercises as secure the normal motility of the articulation. But perhaps the most important results from the use of passive movements for their local effects are seen in the prevention of muscular degeneration. The nutrition of muscle is promoted in great measure by *active* exercises, which are to be hereafter spoken of; but these passive movements also bear an important part in preventing that muscular atrophy which is the result of want of use, and which arises in some forms of palsy in essentially the same manner as it is occasioned by a compulsory loss of function from ankylosis of a joint, or during the confinement which the treatment of a fracture requires. The thermometer often shows an increase of one or two degrees Fah. after a thorough *massage* of a limb, and, if motility exists at all, the muscular tone is always temporarily increased. The electro-muscular contractility is often markedly improved by the same means. When voluntary control of the muscles has been lost, it is essential to prevent this atrophy by supplying an artificial passive exercise, either by means of electricity or by manipulations, to the end that when a restoration is effected the volitional effort may not expend itself upon degenerated muscular fibre. When electricity cannot be employed with safety—for

instance, in the early stage of a paralysis from central lesion—the movements and manipulations offer themselves as worthy substitutes; and even when galvanization or faradization is not contra-indicated by the condition of the patient, not only may they be used with advantage in combination with electricity, but often indeed without detriment in its stead. That passive movements are quite competent to arrest this atrophy from disuse, would seem to have been established by Reid's experiments, which showed that if the nerves distributed to two limbs be divided and the muscles of one limb be left at perfect rest, whilst the other is passively flexed and extended several times in the course of each day, the former set will undergo atrophy, and the latter will retain their normal size, weight, and structure.

It is scarcely necessary to add that it is not to be expected that a means which is chiefly local in its action can influence to the degree which these experiments exhibited, that muscular atrophy and degeneration which is an *essential* part of some varieties of palsy.

The second, or remote objects—for the promotion of reparative processes at the seat of the paralyzing lesion—may be attained in two ways by the use of passive movements. In the first place, mechanical force, which is applied at the periphery, may be transferred as a remedial agent to the central nervous system, just as electricity when applied at the periphery may influence reparative changes in nerve-centres which have undergone serious lesion. We know that peripheral applications of either agent do exert an influence upon nerve-centres, for clinical observation teaches us that good effects follow a careful and proper use of them, and that dangerous signs of central irritation are excited by an injudicious use of them.

Under the latter circumstances electricity and the movements give rise to symptoms which are closely allied: headache, flushed face, excited circulation, and general discomfort. While there can be no doubt that, for therapeutic purposes in this special direction, electricity is by far the more powerful in its action, there are in favor of the substitution of movements in its place, at least in all doubtful instances, the facts that the general disturbance which an excessive use of the mechanical processes may give rise to, is not likely to be as severe as when electricity has been improperly applied; and that the bad effects from the former pass off more quickly and with much less subsequent exhaustion.

The second method of producing a remote effect is by a general application of passive movements to the whole body. In a palsy which interferes with or prevents locomotion, a considerable part of the consequent disordered digestion, general feebleness, and other symptoms of constitutional depression, may depend upon the absence of the usual and necessary bodily exercise; and it then becomes desirable to add to the local treatment a general artificial exercise, to promote healthful nutrition, and to keep up a good appetite and digestion. The kneadings and other manipulations should therefore be applied to the whole body, for when properly used they add most unquestionably in this indirect and secondary way to the completeness of the recovery. As thus employed they really become part of the hygienic treatment, and should be classed with cleanliness, fresh air, and diet.

But it is in accomplishing the third object which is to be aimed at in the treatment of palsy, the re-establishment of voluntary control over the muscles, that the use of movements is pre-eminently advanta-

geous. The local use of passive exercises to affect the nutrition of paralyzed parts of the body may be supplanted very often by electricity, and, indeed, in some instances, especially where direct stimulation of nerve-tissue is required, the employment of electricity may be much more useful than they. Their secondary and remote effects upon cerebral disease or lesion of the nervous system are to be classed, as we have seen, among those which many other stimulant, tonic, or nutritive agents are capable of producing. But when we seek to repair the damage to function which a limb has suffered from paralysis, to renew volitional effort and to re-establish muscular obedience, there is nothing which can be substituted for systematic active exercises. Of course, the applicability of special gymnastics to any particular case of paralysis is determined by the nature of the lesion upon which it depends. In a paralysis arising from the pressure of an exostosis, an aneurism, or other tumor, or from progressing disease in the brain or spinal cord, they could be of little value. They are chiefly appropriate to the treatment of those palsies in which shock or want of use enter as prominent factors in the production of muscular inability, where functional disturbance predominates over organic change. Let a case of cerebral hemiplegia serve in illustration of the manner in which they are to be used. There exists in the early history of this variety of paralysis a period during which the nutrition of the paralyzed limb is almost at a stand-still, and then the passive manipulations and movements may be used, as we have already seen, to add to the comfort of the patient, and also to promote the renewal of active nutrition. Until this period of inaction is at an end, nothing further is to be aimed at. But with the return of activity in the nutritive processes, it becomes the physician's office to endeavor to restore to his patient his voluntary control over his useless limbs. Something more is to be aimed at now than the mere stimulation of muscular growth by passive manipulation and electricity. He is to seek to bring together the injured brain and the powerless muscles, and to restore their relation as nearly as may be by practising his patient in directing his will-power to the ordering of certain movements and his muscles to the execution of them. Beginning, then, at as early a period as is consistent with success (let us suppose this to be before the paralytic has recovered any voluntary control), his first step is to put his patient in an easy position, either lying or partly lying, with every part of the body completely supported, and with every muscle completely at rest. This preliminary is necessary, so that the whole effort which is to be made may exert itself upon the set of muscles which may be selected to receive it, and that no portion need be expended in muscular action to sustain the body or any of its members. The physician then takes a paralyzed arm or leg in his hands and directs his patient to concentrate his will upon the execution of a certain movement, and at the same time he slowly and steadily moves the limb in the direction indicated. This is repeated a few times with intervals of rest, and the treatment ends for that occasion.

The effort, though gentle, should be concentrated, well-sustained, and determined, in order to accomplish which the will of the operator should always operate through the patient. It is not enough that the patient be told what he is to do, and then be left to do it as well as he can—for inability to do this is the essence of his disease—but, in everything he does, he must act only under a command. A kind but determined command is followed by an increased desire,

which is the most favorable condition for an effectual volition, because a volition thus begun commences at its maximum power, and continues full and well-directed to the end. Although the operator himself actually makes the movement which is perceptible to the eye, it is more to secure the *morale* of the patient—for he sees it move while he is trying to move it; he cannot tell how much of the movement belonged to himself, but feels and hopes that he helped some; and, as his effort was slight, perhaps he could do more.*

After a while, be it more or less, as the peculiar conditions of the case may determine, the physician will observe that a muscular effort on the part of the patient is perceptible to him, as the volitional impulse towards the execution of the different movements is put forth. Though the patient's consciousness cannot yet appreciate its existence, the physician recognizes, through his muscular sense, that in executing these movements of the limbs for his patient there is not the same amount of muscular effort necessary on his part that was demanded at the beginning, and that the difference, slight though it may be, is supplemented by a returning power in the palsied muscles. At length a subjective recognition comes, and voluntary motion is an established fact. Thus we see that these regulated exercises serve to shorten the period of helplessness, by bringing to a patient's mind a realizing sense of the existence of power in his palsied limbs, which assuredly could not so quickly be manifested if such repeated trials were not made.

"Suppose a force of two pounds of muscular contraction to be capable of raising the arm; if we began with a force of only one ounce, it might be increased to thirty-one ounces, and still the arm remain unraised; but the most hopeful change has been going on in the nervous and muscular tissues, while yet there is no palpable result." †

In this one sentence is contained the whole argument for the special use of movements which is under consideration.

If, now, the patient be left to himself, he will undoubtedly continue to improve, and to a certain extent regain control of his limbs; but that control will not be as thorough and complete as it would have been made by a continuation of the educational exercises. We should seek through their agency to reduce the ultimate impairment in function to that amount which is inevitably dependent upon organic change, by eliminating those defects in movement which habit is prone to set up. At first the active exercises should be of the simplest nature and of short duration, for their object is the education of volitional effort, and not the development of muscle. The patient must not be tired at the time when they are commenced, nor when they are finished. Far better is it, for the object in view, for him to make one strong and thorough attempt to execute a movement, than to make a dozen feeble ones; for it is easy, through a succession of tedious and imperfect efforts, to acquire bad habits of movement which will impress themselves by repetition upon the centres of motion, and stand in the way of subsequent improvement in function. When the restoration of power becomes more pronounced, and simple movements, such as extension and flexion, can be executed without much effort, it is of advantage to combine the unaffected limbs with the paralyzed in the exercises; for when the ganglia put forth the motor impulse to both limbs at once, the weaker muscles act

to a certain degree automatically, and the perfect method of their opposites is unconsciously acquired. Gradually the more complicated manœuvres are introduced into practice, until at last the patient reaches that point of perfection in movement to which the nature of his disease permits him to attain.

The use of movements—active and passive—in the treatment of paralysis is more closely allied to electrization by the galvanic and faradic currents than to any other therapeutic agent which is in use. Some of their points of similarity and of difference have already been pointed out; but, in concluding this paper, it may be well to look at them once more in regard to the practical effects of each. We have seen that, in exciting a local nutritive influence upon atrophied muscles, or upon muscles which are liable to undergo atrophy, their effects are closely similar, and that they may often be used alternately, or one instead of the other. It is not unlikely, too, that the claims of both should be equally divided in reference to the remote constitutional effect from applications at the periphery. As a means for diagnosing the seat of lesion, and of acting directly in a therapeutic way upon the cerebral nervous system, or its distribution, the galvanic and faradic currents certainly possess powers to which a treatment by movements alone cannot pretend. But, on the other hand, when in the early stage of some of the palsies electricity cannot be safely employed, the movements offer themselves as valuable substitutes to promote nutrition locally and generally, and to add materially to the comfort of the patient. The joint-affections which have been mentioned as arising in the course of paralyzes of the extremities, find a prophylaxis as well as cure in passive exercises; electricity is of much less value for such purposes. And for the restoration of perverted function—the ultimate aim of our treatment—the active exercises, when properly practised, enable the physician to carry forward his treatment far beyond the point where electricity alone ceases to be useful. It is probable that hereafter the use of the galvanic current, in combination with systematic rhythmic exercises, will be regarded as an important advance in the treatment of paralysis. The recent experiments of Doctor G. V. Poore,* show that in certain conditions the passage of a mild galvanic current through muscles, or the nerves which supply them, increases the susceptibility of those muscles to the stimulus of the will, *while the current is passing*, and that ultimately their voluntary power is increased. Duchenne observes that the excitability of motor nerves or muscles by the induced (faradic) current is in many instances determined by the stimulus of the will. In other words, that while the induced current is unable to excite contraction, motility may return in response to volitional effort, and that subsequently the muscles may respond to the electricity. In such instances, the educational treatment by special exercises would be far superior to the use of that form of electricity alone, although the combination of galvanization with the exercises would very likely be an improvement upon either.

A CENTENARIAN.—The *Lancet* of Jan. 30th, gives the account of a post-mortem examination by Sir G. Duncan Gibb, M.D., of an old woman, known as the Tring or Hertfordshire centenarian, who, by well authenticated records, was, at the time of her death, within three months of one hundred and eleven years old.

DIFFUSED GANGRENE OF THE LUNG.

(A PAPER READ BEFORE THE MEDICAL SOCIETY OF
THE COUNTY OF ALBANY, N. Y.)

By F. C. CURTIS, M.D.,

ALBANY, N. Y.

JOHN M., æt. 22, fishmonger; American, of Irish descent.

The patient is of tubercular antecedents, his father having died of phthisis. He has heretofore been pretty healthy, though subject to cough on slight exposure. Has led a rather wild, irregular life, but not so as to materially undermine his constitution. Has been in-temperate.

July 27th, 1874, he came to the office complaining of the usual effects of hard drinking, having been on a "bout" for a fortnight. He was not heard from again until Aug. 14th, his wife then reporting that he was having a severe diarrhoea, and that he had not been well since last seen. He had continued to drink more or less until recently, and during the time had received a pretty severe pounding, though no definite injury had been inflicted. Aug. 22d, a week later, I was requested to see him, and found him at a neighbor's house, sitting by the window. He was quite weak, but too restless to stay at home and in bed. His diarrhoea was very profuse, the stools containing considerable blood. He also had nausea and vomiting. A disagreeable fecal odor was noticed, which had been remarked for two weeks back, attributed to unclean habits. His countenance was rather dusky, respiration hurried, and he had a dry cough. The diarrhoea only was prescribed for.

Next day he was again found away from home, though he had to be assisted in getting there, the weakness much increasing. Diarrhoea was checked, but lung symptoms were more marked. On examination of the lungs, there was found complete consolidation posteriorly on the right side, there being clear tubular breathing over the lower half, most marked at the inferior angle of the scapula.

Next morning I found him completely prostrated. There were mucous rales over the lower two-thirds of the right lung, and evidence of commencing softening. He had no pain. Respiration was hurried, being about 36; but he did not complain of dyspnoea. Cough was moderate, and he expectorated a thin tenacious sputa, of a dark, prune-juice color, extremely fetid. His breath also had the same odor, especially on coughing. This odor struck me as feculent, with a nauseating, sweetish character. It filled the room, and would turn any but a stout stomach. Tilden's preparation of bromo-chloralum was used as a disinfectant very profusely, and it may be noted that it answered the purpose well, making respiration, except in the immediate vicinity of the patient, quite endurable.

I supposed that the case was one of gangrene of the lung coming on in the course of pneumonia. Active stimulation was adopted, with hardly a shadow of hope that it would avail anything. He rallied during the day from his prostration under the sharp spurring of his vital forces, but next morning was found in a low, typhoid condition, with sordes on the teeth, lips, tongue, an immobile expression, and a mild delirium, from which he could be roused. His respiration continued about 36, with little variation throughout, the pulse being 110, until toward the last when it rose to 140. The temperature unfortunately was not taken. He roused up to expectorate, the amount of sputa being considerable. The symptoms presented during the four days that he lived after this collapse varied but

little from these given. Stimulants were perseveringly used, keeping up his strength a little. He died on the morning of August 28th.

The autopsy was made twenty-four hours after death.

Thorax.—Both lungs were remarkably distended, filling their cavities fully, and being extremely firm and incompressible, so as to hardly allow the passage of the hand between them and the chest wall. There were feeble adhesions only of the right pleura throughout, hardly more than a sticking together of the surfaces. There was no effusion on either side. Turning the right lung out and laying it open posteriorly, there was found a large cavity, having a centre about the central portion of the lung, from which branching cavities went off above and below, and at points coming very near the surface. It had a capacity of about 24 ounces. There was contained in it a thick, dark-colored fluid of exceedingly offensive smell. Bands of tissue ran across the cavity, having not yet been destroyed. It was lined with lung tissue of a dark-grayish color, friable, and breaking readily between the fingers. This extended several lines, variable in different places, back from the cavity, merging gradually into the condition of the rest of the lung, which was deeply congested, solidified—just as is found in the stage of red hepatization of pneumonia. No obstruction of the bronchial tubes was found; neither was there evidence of pulmonary embolus. The left lung was healthy. There was no trace of tubercular deposit in either lung. The bronchial glands were enlarged, and contained a dark, pigmentary matter. The heart was quite healthy.

The liver was large and fatty. Both kidneys were large, of dark color, the capsules adherent, and the Malpighian tufts partly destroyed. Other organs of the body were not found specially diseased.

Here we have an undoubted case of diffused gangrene of the lung, a disease we rarely meet with. This infrequency is shown by the analyses of autopsies given by Flint: of 1,069 post-mortem examinations at Vienna there were only 5 cases of pulmonary gangrene (and it is so general to make these examinations in the Hospital there that such cases could hardly escape being looked into); among 3,437 made at Prague there were 75; while Fuller says that during ten years there were but 19 cases in the St. George's Hospital, London. Trousseau states that he has seen but two cases, aside from those of traumatic origin. The circumscribed as well as the diffused forms of gangrene are included in the above, and cases in which so extensive a destruction of lung tissue takes place, as in the case given, must be extremely rare.

The causes of gangrene of the lung and the pathological conditions giving rise to it are somewhat obscure. Gangrene, in general, is induced by cutting off the blood supply of a part. Aside from this mechanical method of production, an element of causation may exist in impairment of the condition of the blood.

One of the direct causes of gangrene of the lung is embolism of the pulmonary artery. Flint doubts this, since the lung depends for nutrition on the bronchial arteries, and he has, too, met with a case in which the left primary division of the pulmonary artery was entirely occluded by a calcareous mass of tuberculous origin without the occurrence of gangrene. Possibly this is to be accounted for by its slow formation, for Trousseau gives a case where an embolus of the pulmonary artery occurred in the course of phlegmasia dolens which was followed directly by symptoms of gangrene, and at the autopsy that part of the lung supplied by the artery was found sphacelated. He adds that Vir-

chow recognizes this cause of gangrene, although this vessel is not concerned in the nutrition of the organ.

Splacelation of the lung has been known to occur in the course of pneumonia. This statement is doubted by Dr. Alonzo Clark, and was by Lacunee, but I give it on the authority of Flint, Niemeyer and Da Costa. Flint gives two cases, only one proving fatal. Trousseau states that he has never seen a case, but adds that it has been observed. Niemeyer says that during the culminating period of pneumonia this condition may arise, absolute arrest both of circulation and nutrition being caused by the inflammatory stasis.

Gangrene of the lung has arisen in the course of exhaustive diseases, either general or affecting other organs. Among these may be cited diabetes, small-pox and typhoid. In the same category may be placed the occurrence of diffuse gangrene in the lungs of drunkards, which is mentioned as liable to take place by Niemeyer. The reason for this he says is difficult to explain, but it seems probable that it is from the debility arising from deficient nourishment. It has been observed in persons reduced by a lack of suitable nourishment alone, and its frequent occurrence in lunatics may perhaps be accounted for by this also. Possibly the first step in the tissue change is an inflammatory disturbance of the lung, and the reason for the selection of these organs may be sought for at the same time that we inquire why pneumonia is so apt to set in as intercurrent to capital operations.

Finally, among the causes of this disease may be mentioned traumatic causes, including the passage of foreign bodies into the lungs. Articles of food passing into the bronchial tubes decompose, probably irritate and inflame, and at length set up a necrosis of the surrounding tissues.

In the case which I have narrated, I supposed gangrene to have followed pure pneumonia. The post-mortem, however, showed the pneumonia, which actually existed throughout the whole lung, to be only in the stage of red hepaticization, while a large portion of the lung was already destroyed and sloughed away. This could not have taken place in the short space of time that the pneumonia had existed. More than this, the fetor, so marked during the last few days, had been noticeable before, though attributed to uncleanly habits. Search was made at the autopsy for evidence of a foreign body in the air passages, and for obstruction of the arteries, and their not being found does not of itself preclude the possibility of this cause. But there was nothing in the history of the case, so far as obtained, that pointed to the occurrence of either of these accidents. I conjecture that the case is to be classed as one of those occurring from debility brought on by protracted intoxication. It would seem that circumscribed gangrene began some time before he was seen, affecting only a very limited portion of lung tissue, that it existed as circumscribed gangrene for nearly or quite two weeks, during which time the peculiar fetor was noted by his friends although he was about all the time, that it then became diffused and extended rapidly, destroying the life of a considerable portion of the lung, which finally broke up and sloughed away during the last few days that he was under observation. Five days before he died it was clearly consolidated, and in the course of twenty-four hours was softened and being thrown off, accompanied with profound prostration. We might, by a little stretch of the meaning of the word, call it a case of *idiopathic* gangrene.

The diagnostic value of the symptoms in this case demand a word. Those presented were the peculiar odor of the breath, particularly pungent in coughing, the odor and appearance of the sputa, the great pros-

tration and the general symptoms pointing to disease of the lung. Trousseau says: "When I review the recollections of my personal experience, when I consult what has been written on this disease, I am struck with the inadequacy of the signs by which to determine the existence of gangrene of the lung."

The leading symptom is the characteristic odor, prior to the appearance of which diagnosis is impossible. It is, in fact, the only symptom of decisive import. Other conditions produce fetor of the breath and sputa. Among those mentioned are pleurisy, attended with perforation of the lung; tuberculosis, in which cavities having formed, sloughing of lung tissue in them takes place; fetid bronchitis, produced either by a superficial slough of the bronchial mucous membrane or by the secretion assuming a fetor apart from this. Three distinct kinds of pulmonary fetor have been described—that of ozena, of feces, and of gangrene: the first applying to fetid bronchitis and to bronchorrhoea, the second to pleurisy, in rare instances with fetid effusion, the third to gangrene. But in the case of gangrene which I have given, the odor seemed distinctly fecal, and I should hardly think any reliance was to be placed on this sub-division. It was suggested by one physician, who saw my patient with me, the possibility of it being a case of rapid tuberculosis. While this symptom of fetor of breath and sputa is thus liable to misinterpretation, yet, taken with the history and course of the disease, it leaves little doubt as to the nature of the case. Prior to the softening and expectoration with formation of cavity, I do not think a diagnosis can be made. This course of the disease, however, is not at all uniform. The onset varies with the cause giving rise to it. There is, too, a wide difference in the impression made upon the system by circumscribed and diffused gangrene. Gangrene may be said usually to set in as a case of pneumonia. Then comes the prostration from blood-poisoning. This may not be marked for weeks, the patient being about and showing little evidence of his serious malady. If the gangrene be diffuse, however, profound prostration comes on at the beginning—the respiration is rapid, the sloughing tissue is expectorated or swallowed, physical signs of a single cavity at the central or lower portion of one lung are found, and accompanying all these is the horrible, sickening smell—an assemblage of symptoms which cannot leave a doubt concerning the character of the disease or its certain termination. Doubt can only arise when the gangrene is quite circumscribed. It is a fortunate fact that we have but rarely to deal with a case of diffused gangrene of the lung, but the possibility of the occurrence of these rare diseases at any time makes the extended consideration of the few cases that do come under observation, valuable.

HOMEOPATHY IN THE ST. LOUIS HOSPITALS.—An effort is being made to introduce homœopathy into the hospitals of St. Louis, and the editor of the *Missouri Clinical Record* says: "Once admit the homœopaths, and in a short time, every other 'ism' and 'pathy' under the sun will claim the same privileges, and as justly too; and it will not be long before the people will judge of these things in their true light, and common sense will prove the beneficent handmaid of science.

"Let our Boards of Health admit to practice in our hospitals the eclectic, homœopaths, and others who may desire it; but let it at the same time be required by law that there be kept the strictest accounts of the diagnosis, treatment, and all other matters appertaining to the patients under their care."

THE PROMPT TREATMENT OF ACUTE DISEASES OF THE THROAT.

By F. A. BURRALL, M.D.,

NEW YORK.

SOME time since I was called to attend a middle-aged, married, American lady, who had been suddenly taken ill with nausea, sore throat, and fever. No eruption accompanied the attack, and convalescence ensued in about five days. Ten days later the youngest child was seized with scarlatina simplex. On the day succeeding the first of the youngest child's illness (Tuesday), the eldest, who had suffered from scarlatina at a previous period, was attacked, however, with sore throat and fever, unattended by any eruption. The nurse had severe tonsillitis, which commenced on Wednesday, and on the following Friday the third child showed febrile symptoms, which were duly followed by a scarlatinal eruption. During the sickness of these patients it was ascertained that a child in an adjoining house had been attacked with severe scarlatina two weeks before the indisposition of the lady to whom I was summoned. There is every reason to believe that the same poison was illustrated in distinct forms by each of the above attacks. Hence the importance with which an apparently simple sore throat may be invested, and it is at least wise to regard every acute attack of what is generally termed "sore throat" as a "questionable shape" which may envelop the contagion of scarlatina.

Similar considerations apply to diphtheria. It is not always easy to decide at once whether to apply so grave a term to a few white flecks upon a tonsil, which may be but alterations in the follicular exudation. Yet that variety of diphtheria must not be forgotten which remains for a few days under the form of a comparatively insignificant ailment, and quite suddenly develops into a fatal disease.

In his valuable work on "Diseases of the Throat," Dr. Solis Cohen refers to a malady which he terms "membranous sore throat," and which is thus described:

"There is a variety of sore throat, almost always more or less met with at all seasons, characterized by the exudation of a fibrinous material which coagulates into a pellicle or false membrane. These cases are very often mistaken for diphtheria, and account for much of the success claimed for the various treatments of that disease. For apart from the immediate danger sometimes attending the mechanical obstruction in cases implicating the larynx—cases, however, which are very rare—the tendency of this affection is to recovery; while a similar tendency in diphtheria is, as we shall see, doubtful. This form of sore throat is often met with during the prevalence of diphtheria, and may sometimes be a starting-point of that disease. Discrimination is therefore of paramount importance."

"The membranous deposit is often found upon the ulcerated surfaces of mucous membrane, and also upon cutaneous ulcers, and the broken cuticle of blistered skin. It presents a similarity to the deposit found upon similar surfaces in diphtheria, but does not constitute diphtheria, there being an entire absence of the toxic symptoms of that disease."

"It has already been stated that when diphtheria is prevalent, common membranous sore throat may invite

an attack of diphtheria; and that it is often met with during the prevalence of diphtheria. If, therefore, there be any doubt as to its nature—and doubt may readily arise under such circumstances—the safest plan for the practitioner would be to treat it as if it were diphtheria."

There can be no question that the advice here given to treat any doubtful case of this kind as diphtheria is the "safest plan." Such a case came under my care, which I was disposed to regard as membranous sore throat, after reading Dr. Cohen's description of that disease. It was treated, nevertheless, as diphtheritic, and proved to be diphtheria. Evidently an error in diagnosis might easily occur; in fact, were it not for the distinguished names which endorse this title one would readily be led to question whether this disease were not essentially diphtheritic, so strong are the points of resemblance. If we regard diphtheria as primarily a local disorder which afterwards becomes constitutional by penetration and absorption of a local poison, how difficult must it be to decide that the milder cases of membranous sore throat are not cases of diphtheria in which no absorption has taken place. As is well known, some constitutions seem almost proof against what are known in general terms as contagious diseases.

Admitting, then, that sore throat, even of a mild character, should not be neglected, the question of treatment requires consideration. What method shall be adopted? There is strong reason to believe that scarlatina and diphtheria are connected essentially or indirectly with the development of germs, and the local remedies used should therefore be taken from the class of antiseptics. Such remedies have been used even long before the germ theory was in any favor, apparently because they were found of use. Germ life is a kind of cell life, and in order for cell life to continue, investigations have shown that the fluids which run into and out of the cell must be sufficiently fluid to permit of easy transit. This circulation is impeded or annulled if these fluids are coagulated. There are also agents, such as chromic acid, carbolic acid, alcohol, chlorine, iodine, sulphur, and permanganate of potash which probably by some different chemical action destroy fungoid life. Carbolic acid is said to produce this result, arresting albuminous metamorphosis. A moment's thought will show that some of those agents, which have been esteemed both as remedial in throat diseases and also as antiseptics, consist of antiseptics in combination with astringents. Of these are persulphate of iron, sulphate of copper, carbolate of zinc. Bare experience, unattended by any theoretical knowledge, seems to have led to the adoption of several such remedies.

These thoughts with regard to the action of certain medicines in sore throat are introduced because it is sometimes interesting to trace out the causes of things, and in the present instance to bring forward a reason why remedies have found favor in acute diseases of the throat. The main point, however, which it is proposed to present in this article are, that *no acute sore throat should be neglected, however mild, and that antiseptics should form a part of the local treatment.* Such attacks should not be neglected, both because they may be *essentially* grave diseases, and also because, if treated very early, early resolution often follows.

DR. T. LANDER BRUNTON, who succeeded the lamented Anstie in the editorship of *The Practitioner*, has recently been elected Assistant Physician to St. Bartholomew's Hospital.

Progress of Medical Science.

TINCTURE OF ARNICA A DANGEROUS APPLICATION.

—Dr. James C. White has an article in the *Boston Med. and Surg. Journal*, for January 21st, 1875, on the poisonous action of tincture of arnica on the skin. He relates three cases, where its use as a lotion for bruises occasioned severe attacks of acute eczema. Dr. White is inclined to believe that such results are more common than is generally known. The use of arnica as a household remedy is exceedingly extensive, and the reason that the poisonous effects often produced upon the skin do not lead to its disuse, is that the true nature of these effects are seldom recognized, but are attributed to the original injury for which the arnica is applied. Whatever beneficial results may follow the use of that tincture Dr. White would ascribe wholly to the alcohol. Hebra has long ago entered a protest against the use of this supposed remedy, and its irritant properties are described by Tilbury Fox. Dr. White thinks the profession should cease to accord to so useless and dangerous a drug a confidence to which it is in no way entitled.

PSORIASIS TREATED BY THE INTERNAL USE OF CARBOLIC ACID.—Moritz Kohn, of Vienna, has recently published in the *Arch. f. Derm. u. Syph.*, the record of numerous cases of various forms of skin diseases and syphilis, treated by the internal administration of carbolic acid. Cases of psoriasis, pityriasis rubra, prurigo, pruritus cutaneus, and certain non-ulcerative forms of syphilis, improved greatly or were wholly relieved after the use of this remedy, during a period of from four to seven weeks. It was administered in the form of pills made up with liquorice, each pill containing one grain of carbolic acid. At first, from six to nine pills were given daily, and later from twelve to twenty. He noticed that even after a small amount was taken it could be detected in the urine, though it was never the dark thick urine, smelling of tar, which has been observed after applications of carbolic acid to open wounds. In illustration of this method, he mentions two cases of psoriasis occurring in his own practice. One was a man twenty-six years of age, who took from four to sixteen grains daily, and at the end of five weeks there was entire disappearance of the disease. The only adjuvant in the treatment was cod-liver oil, which was used as an inunction in the later stages. After the lapse of three months there had been no recurrence of the disease. The other patient was a girl, thirteen years of age, with whom the same treatment was pursued, but without the cod-liver oil, and she recovered entirely of the disease at the end of four weeks. She never took more than four grains a day. At the expiration of four and a half months there had been no relapse.—*Allg. Med. Central-Ztg.*, No. 103, 1874.

AN AGED PRIMIPARA.—Dr. Würzburger, of Bochem, was called in to see a stout countrywoman, who complained of severe pains in the back and belly. A very brief examination convinced the doctor that the woman was in labor, the parts of the fœtus being easily made out. When the woman was informed of her condition she protested against its possibility, saying that she had been married for over twenty years, was now past forty-eight years of age and had never been pregnant. She attributed the absence of menstruation for the past nine months to her change of life, which she believed had come. She was surprised when four hours later a well-developed female child

was safely delivered, forceps being required on account of the inefficiency of the expulsive efforts. The mother made a good recovery, although there was not the slightest effort on the part of nature to establish lactation. Menstruation, however, returned regularly. A curious feature of the case was the complete change which soon took place in the constitution and appearance of the woman. From being stout, erect and vigorous, she became thin, wrinkled, bent and gray. Some interest may also attach to such a case in a medico-legal point of view, from the fact of the woman being completely unconscious of her condition up to the moment of her confinement.—*Allg. Med. Central-Ztg.*, No. 103, 1874.

SACCHARINE URINE AFTER POISONING BY NITRO-BENZOL.—Two cases of poisoning by nitro-benzol, with suicidal intent, were observed at the clinic of Prof. Frerichs, and Dr. Ewald has reported them in the *Berl. Klin. Woch.*, No. 1, 1875. They both occurred in young women aged twenty-six and eighteen years respectively; the former swallowed about 60 grains, the latter rather over 150. Both patients recovered. Dr. Ewald's attention was particularly directed to the examination of the urine for sugar in these cases, because he had found it in the urine of rabbits and dogs poisoned by nitro-benzol. In the urine of the first and lighter of the two cases, there was no reduction of the oxide of copper to the sub-oxide, by Trommer's test, but the doctor was led to infer from the large amount of sulphate of copper held in solution by the caustic potash that either sugar or some substance closely allied to it, might be present in small amount. In the urine of the second and severer case, which was obtained by the catheter six hours after the poison was taken, he satisfied himself, however, of the presence of sugar. The clinical history and treatment of these cases presented no features of special interest, and did not differ materially from the cases that have been published by others. The characteristic features of poisoning by nitro-benzol, in regard to which there is great uniformity among authors, are the following:

1. A period of latency, seldom exceeding half an hour, which ends with the access of headache, and sometimes vomiting.
2. A striking cyanosis of the skin and mucous membranes, not due to disease of the organs of respiration and circulation.
3. A deep stupor, in which the patient is wholly unconscious of external impressions.
4. A strong smell like bitter almonds. There is also, so far as investigated, a brownish coloration of the blood. The following points of difference should be noted between the action of nitro-benzol and the true oil of bitter almonds, containing hydrocyanic acid, with which it is often confounded, both by name and by its smell. This latter acts with lightning-like rapidity, and produces pallor of the surface, while the former, as stated, has its period of latency, its cyanosis, and moreover the peculiar coloration of the blood, and sugar in the urine. As to treatment, the author urges the necessity of promptly and thoroughly emptying and washing out the stomach, and recommends as a ready method of doing this, the use of a piece of the ordinary flexible gas tubing, which he says can easily be made to answer every purpose when the end is smoothed off, eyes cut at one side and the instrument properly oiled. The list of cases referred to by the author is inaccurate.

REVIEW OF THE MODERN METHODS OF TREATING STRICTURE.—At a meeting of the Medical Society of London, held Dec. 21, 1874, Mr. Teevan read a paper

on the above subject. He stated that the methods of treating stricture might be ranged under the following heads, and that he had tried each method excepting electrolysis. 1. The expectant plan, which confined the patient to bed, trusting that the symptoms would disappear by rest, warmth and purging. The method was not in favor on account of the sacrifice it entailed on the patient, and ought to be reserved for cases of impassable stricture, to enable the surgeon to introduce an instrument. It often failed completely. 2. Continuous dilatation. Most useful where gradual dilatation had failed, or where it was desirable to get the patient well in a few days. In some cases the treatment could not be carried out on account of the irritation it set up. 3. Gradual dilatation. This treatment was most in favor with the majority of surgeons, for it allowed patients to pursue their avocations without interruption, and it was devoid of the slightest risk. There were certain drawbacks to the treatment, chiefly caused by the use of an imperfect gauge and instruments. If the French gauge and soft French instruments were employed, failures would be rare. 4. Caustics. Most useful in certain cases of impassable stricture, to open up the mouth of the stricture, and enable the surgeon to introduce an instrument. The treatment did not deserve the wholesale condemnation passed upon it. 5. Electrolysis. The facts were too few to enable a correct judgment to be formed. The treatment was still *sub judice*. It deserved a fair trial, however. 6. The plan of sliding one instrument over another. Useful in cases where there was a false passage, or where the difficulty of treating the case arose not so much from the tightness of the stricture as from the tortuosity of the urethra. 7. Forceful dilatation, which included the so-called "immediate treatment," or "dilatation forcée," more properly termed "divulsion" by Voillemier and the American surgeons. This treatment was rapidly falling into disuse. In France the operation had been almost entirely abandoned, and in Great Britain and America surgeons were constantly relinquishing the practice. In Germany the operation had never been popular. The objections to the treatment were that it was, so far as could be ascertained, the most fatal of all operations for stricture, and that the relapses were speedy and aggravated. In London alone a large number of deaths had occurred after the operation. He always had under his care a number of patients whose strictures had been split up by other surgeons, and whose relapses had often taken place in spite of the utmost care and attention. 8. The various methods of urethrotomy. In France internal urethrotomy was the stock operation. It was in harmony, he said, with all the teachings of surgical pathology and experience, and was making rapid strides in all parts of the world. In Great Britain and America it was supplanting forcible dilatation. There was but little risk attached to the operation, and its results seemed more permanent than those following other operations. He looked upon "subcutaneous urethrotomy" as the operation of the future, and preferred it in all cases where it was applicable. External urethrotomy ought to be reserved for cases of horny or resilient stricture, complicated with perineal abscess or fistula. The principles of treating stricture had been correctly summed up, upwards of thirty years ago, by M. Auguste Mercier, and might, he said, be thus briefly translated: "Dilate where you can, cut where you cannot." A lengthy discussion followed, all those taking part in it supporting Mr. Tevan in his condemnation of forcible dilatation. It is said, however, that among those absent from the meeting were Mr. Holt and Mr. Hill, the

well-known advocates of opposite views.—*The Lancet*, Jan. 9, 1875.

SALICYLIC ACID.—Prof. E. N. Horsford has a letter from Professor Schwartz, of the University of Gratz, giving some account of an important communication made at the recent German Scientific Congress at Breslau, an extract from which he publishes in *The Boston Medical and Surgical Journal*.

In the chemical section the most important thing was the exhibition of the salicylic acid now produced in large quantities by the process of Kolbe. It is made from C_{12} , $H_6 O_2$ and $Na O$, $H O$ (phenol-sodium), into which is conducted dry carbonic acid at a temperature of $170^{\circ} C$. There is formed salicylate of soda, which, decomposed by hydrochloric acid, precipitates the salicylic acid. This is the best disinfecting agent known. It is without odor, tasteless, not poisonous, and, even in small quantities, absolutely preventing putrefaction. Meat immersed in a solution of salicylic acid, in an open vessel, remained perfectly sweet for weeks. It prevents milk from coagulation. Fruits do not become mouldy, and wounds heal without festering. In the case of a patient whose leg was amputated, the wound was sprinkled with a little salicylic acid, and bandaged for six days without being touched; it was then found to be healed over without the slightest formation of pus.

It is easy to see what enormous significance attaches to this discovery. The transportation of meat, the preservation of bodies; of anatomical and zoological preparations of fish, mollusca, milk, beer, wine, etc., will be greatly promoted. It must be remembered that salicylic acid is perhaps twice as effective as carbolic acid, and that it is wanting in the poisonous and unpleasant qualities which characterize the carbolic acid. Dr. Fr. v. Hayden has erected, at the suggestion of Prof. Kolbe, a manufactory of salicylic acid at Dresden, where one may now obtain the acid at ten thalers per kilogramme (about \$3.50 per pound).* Professor Horsford says: "It may be well to add that salicylic acid is a constituent of the oil of wintergreen (the checkerberry, *Gaultheria procumbens* of New England). Its production from carbolic acid (phenol) on a commercial scale, and so from "dead oil," a familiar product of the distillation of coal-tar, is one of the triumphs of modern chemistry. It promises so much in practical surgery, in securing healing by first intention, in the prevention of pyæmia, and in the arrest of the growth of all forms of microscopic animal and vegetable life that characterize fermentation and putrefaction, that opportunity for experiment cannot be too soon open for all. The article can be imported in small quantities through the mail, and in larger quantities through any of the leading druggists.

SUBSTITUTE FOR LINSEED-MEAL FOR POUULTICES.—The Paris correspondent of the *British Medical Journal* writes that at a recent meeting of the Academy, M. Le Fort read his report on a paper by Dr. Lelièvre on a substitute for the ordinary linseed-meal poultice, which M. Le Fort was charged to investigate. Dr. Lelièvre proposed the "*Fucus crispus*," or carrageen lichen, as it possesses the following advantages: it may be cut into thin plates of the size required and, when steeped in hot water, it softens and swells in a few minutes. This new poultice has been tried by MM. Demarquay, Gosselin, and Verneuil in their respective hospitals, and they have pronounced it to be far superior to the linseed poultice; it keeps moist for more than sixteen or eighteen hours; it does not slip; is inodorous; does not readily ferment, nor does it soil the linen.

* Its present price is about three dollars per ounce.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

New York, February 27, 1875.

OUR MEDICAL CHARITY SYSTEM.

THERE are many questions having reference to the management of our medical charities which invite discussion. Especially is this the case at a time when there are so many of the sick and deserving poor who have a claim upon us. The trouble is not that we are deficient in the number of institutions which offer the requisite aid to the needy, but in the faulty system by which they are managed. In fact, they fall so far short of their avowed intention, that the majority of such as are entitled to their benefits are the least apt to receive them.

One trouble is that there is not enough care taken on the part of those who dispense the charity, to see that it is directed in the proper channels. For this the profession is in no small degree responsible. There is with some physicians such a great desire to improve the advantages which a large experience in the treatment of disease affords that almost every consideration is sacrificed to it.

So far from taking ordinary pains to discriminate between the deserving applicant and the pretender, efforts are made in a contrary direction by soliciting patronage, and thus directly encouraging improvidence and pauperism. For instance, when a new hospital or dispensary is started, it is not an uncommon thing to see placards upon the fences announcing the fact, and a general invitation to the public to avail themselves of the privileges of being treated gratis. Mention of course is made that the appeal is only to such as are unable to pay, but practically speaking, it is a bid for a full house, irrespective of the character and means of those who may fill it. There are so many of these enterprises which are managed in the interest of the attending physicians, who wish, by such a connection, to advertise themselves in the practice of a particular speciality, that it would be contrary to their interests to be too particular in their discrimination of the respective claims of their patrons. Very frequently the

claims for annual appropriations of the Legislature to such institutions, rests entirely upon its apparent use to the community, as proved by the number of persons who have sought to be relieved through its instrumentality. In view of this fact, there is a temptation to swell the list of patients, which is hardly to be resisted by any one who, for individual and selfish motives, wishes to have the institution prosper. For this purpose not unfrequently the same patient is entered two or three different times upon the records, and many other little dodges resorted to tending to create an impression of the usefulness of the charity. Very often the attending physicians, rather than see their projects fail, help to support it by their own contributions. Generally speaking, the problem which presents itself to these medical benefactors is not so much how can we prevent imposition by indiscriminate charity, as how can we secure a goodly attendance upon our classes.

While some physicians would strain a point to seek for this sort of practice, and at the same time quiet their consciences that in the end a good is to be accomplished thereby, there are others who strive in every way to deal fairly towards their institutions, their patrons, and their profession. The fact, however, that in spite of such care so many undeserving ones are benefited, proves the necessity for a great deal of reform in the management of our charities generally.

In suggesting any plan which might tend to mitigate the evils of which we complain, a difficulty presents itself at the very outset. How can the abominable practice of bidding for patronage on the part of some unprincipled individuals be prevented? The answer to this question is by no means an easy one. So long as it is possible for certain ones to use political influence for special appropriations to one-horse institutions, and manage them in their own professional interests, the outlook towards a radical reform is very poor indeed. We are virtually compelled, under the existing circumstances, to endure the system the same as we are required to do with any evil of which there does not appear to be any remedy. The root of the difficulty is to be found, for the most part, in the system of special legislation, which, however it may benefit the individual, is always in the end detrimental to the interests of the community. Such individuals would not do right if they could, and consequently to these any remarks regarding moral, legal, or professional obligations can hardly apply.

The great majority of the attending physicians and surgeons of our medical charities, however, have a desire for reform in the matters of which we speak. Very many take pains to sift the worthy from the unworthy applicants, but even when this is done, we all know how impossible sometimes it is to draw the proper distinction. Then, again, it is hardly to be expected that an attending physician should be a detective, or that his time should be occupied in individual examinations of the pecuniary standing of his dis-

pensary or hospital patients. At best this is a disagreeable task, and should, in fact, be rendered unnecessary by proper management of the board of trustees before the patient should be allowed to present himself at all. The best way to accomplish this, is a subject well worthy the consideration of every one interested in the care of the sick poor.

In many portions of Great Britain the support of the dispensaries depends, as here, upon private contributions. Each contributor receives in return a certain number of tickets, which he can dispense among those who he may deem entitled to receive the aid of the institution. This would appear to be an excellent system, especially when it is understood that no one, except in cases of great emergencies, can receive help, unless provided with a ticket. The trouble has been, however, that the very means taken to prevent indiscriminate charity tends to increase it. Many of these ticket-holders are known to distribute their favors without any reference to merit, and with the sole purpose of increasing their custom as tradesmen, or of making sure their chances for political advancement. The trustees of the institution to which these people may be sent, although they may be aware of the fraud, have seemingly no power to prevent it.

The ticket-plan is, however, a good one, when properly carried out. At least it is the best one which we can adopt, one which offers the least objections, one which cannot seriously interfere with the management of any well-organized institution. The trustees of such should not only be practically but in reality the guardians of the deserving poor, and they should see to it that none others are benefited. We cannot see why, except in extreme cases, every applicant to a dispensary, hospital, or other charity should not come recommended as worthy by some one known to the person who may represent the board in granting admission. If this could be done, we should have the surest means of knowing if any one is really too poor to pay for medical services. There is no one so mean or so poor who cannot obtain a suitable certificate from some responsible person, be he former employee, clergyman, neighbor, or friend. If the various boards would agree to adopt some such plan, and strictly adhere to it, it would be one of the means towards a much needed reform in the management of every charity in the land. Let it be understood that no one can be treated unless he has the card of the managers, and let these latter be sure that none obtain these cards except those who are worthy, and we take an important step in the right direction. At least we think it deserves some sort of trial.

We have more to say upon this subject, which, however, we shall defer to some future occasion.

VIVISECTION.

THE cause of vivisection has no lack of advocates in the world of progressive medicine. France has been

discussing the subject for some years back, and is again interested in connection with the recent prosecution of the Committee of the British Medical Association which permitted the experiments of Dr. Magnin. In England still more enthusiasm is manifested in the defence. The various English medical journals have bestirred themselves to present the subject in its proper light. Of all the statements that have been made none are calculated to do more good than those presented by the *British Medical Journal*, to which, in another column, we call the attention of our readers.

THE CHANGE OF PLACE OF MEETING OF THE STATE SOCIETY.

THE suggestions of Prof. Roosa regarding the change of place for the meeting of the State Society are worthy of consideration. In his communication in another column he recommends some of the well-known summer resorts of the State as best suited for places of meeting. We do not see any objection to this; in fact, they offer very many advantages which the different cities may not be able to give at the time of the year when the meetings are hereafter to be held. In no better way can pleasure be combined with scientific profit. The hotels at that time of the year would be comparatively empty, and the choice of halls for meeting could be made without difficulty.

ALUMNI DINNER OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NEW YORK.—On Thursday evening, Feb. 18th, the alumni of the Medical Department of the University held their annual meeting and dinner at Delmonico's. Previous to the dinner the following officers were elected for 1875:

For President—Chas. Inslee Pardee, Class of 1860. For Vice-Presidents—Alfred L. Carroll, Class of 1855; John R. Dickson, Class of 1842; S. Fleet Speir, Class of 1860; J. J. Peterson, Class of 1870; Thos. C. Finell, Class of 1849; Josiah Gautier, Class of 1843. For Secretary, three years—F. R. S. Drake, Class of 1871; For Treasurer—C. Dixon Varley, Class of 1844. For Executive Committee—Jas. H. Anderson, Class of 1860; D. B. St. John Roosa, Class of 1860; S. Seabury Jones, Class of 1869; Stephen J. Clark, Class of 1861; F. Le Roy Satterlee, Class of 1868; A. E. Macdonald, Class of 1870; Jos. J. Hull, Class of 1858; Daniel H. Kitchen, Class of 1870; Nathaniel C. Husted, Class of 1850; Wm. T. Bacon, Class of 1871; Andrew Otterson, Class of 1844; Edward L. Pardee, Class of 1870.

Dr. James R. Leaming presided at the table, having upon either hand, as guests, Chancellor Crosby, Drs. Charles M. Allin, Thomas R. Pooley, Rev. Dr. Taylor, Hon. W. R. Martin, and Dr. Samuel Hall, of the Park Commission. Chancellor Crosby responded to the toast of "The University of the City of New York." Prof. Alfred C. Post to that of "The Medical Department of the University;" Dr. Allin and Dr. Pooley to the toast to "Sister Alumni Associations;" Dr. Roosa responded to the toast to "The Alumni Association." That to "Our Public Charities" was the source of speeches from Drs. Hammond, Loomis, Gillette, and Anderson; and the toast to "The Press" was answered by a speech from Col. Thomas W. Knox. The toast "To Woman" was responded to by Dr. A. E. Macdonald.

Reports of Societies.

ACADEMY OF MEDICINE.

Adjourned Meeting, Feb. 11, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

DISCUSSION UPON PNEUMONIA—CONTINUED.

DR. LEAMING. It is a well-known fact that inflammatory diseases of the chest, unusually fatal in their results, have prevailed this winter. He regarded the term pneumonia as generic, including all the inflammatory diseases pertaining to the respiratory organs and their appendages, and notably that form of disease which is characterized by plastic exudation into the pleura without serum.

Is the present type of pneumonia different from what we have known during the last twenty-five years? Is it epidemic? and if so, what do we mean by this designation?

From 1851 to 1858 he saw his full proportion of these cases. His patients were among those whose occupation rendered them liable to all inflammatory diseases. His cases at that time were regularly treated with mercury, blisters, iodine poultices, etc., and fatal cases were rare, occurring only when there was some serious complication. Some of the cases went through without treatment, and apparently were better off than those which were treated. Consequently a plan of treatment was adopted which consisted in regulating the digestive apparatus, applying turpentine liniment to the chest, and administering stimulants to those who had been accustomed to their use, together with as good air and diet as could be obtained. The results were very satisfactory, and fatal terminations rare.

In 1859 diphtheria and cerebro-spinal meningitis made their appearance, and preceding them we were visited with an epidemic of ship-fever. Since that time fatal cases of pneumonia have steadily increased in number. And now, instead of regarding it as a simple disease, almost certain to get well, there is a dread of its approach.

The doctor then traced the spread of a disease which broke out among the British troops in Canada in 1812. It reached the Gulf of Mexico in 1820. It was a peculiar type of typhoid pneumonia. Previous to this the pneumonia of the Southern States was not different in degree of fatality from that in the North. What produced the change? The idea designed to be conveyed was, that these epidemic diseases, occurring in 1859 and later, are indicative of atmospherical changes, and that the influences that led to their development have been prolonged, and we are feeling their effect at the present time. Iluxam's observations were quoted with regard to the prevalence of certain diseases when certain conditions of the atmosphere and certain winds prevailed.

If observations had been continued, and accurate meteorological records been made, it is possible we might have known more of the nature of the disease, and known better how to treat it.

Simple uncomplicated pneumonia is rare. Pleuropneumonia is common. This fact was noticed by Iluxam.

The doctor remarked that he had not seen a case of pneumonia this winter that was not one of pleuropneumonia, and he regarded it as the important characteristic of the present epidemic.

The treatment is (1) abortive, (2) careful nursing and watching, (3) expectant. If the patient is seen in time the abortive treatment may be attempted, because if successful the danger is avoided. This may be done by different means. Any agent making a sufficiently sedative impression upon the organic life of the body may do it. It is sometimes done spontaneously. The application of heat or cold may do it. Powerful emetics or cathartics may also accomplish the same result. Stimulant agents, such as turpentine, croton-oil, blisters, etc., may do it. Heart sedatives, such as veratrine, opium, calomel, quinine, may do it. Each practitioner has his selected method by which this end can be accomplished. His own preference was first for the sedative action of calomel, and second for that of quinine. He had found a degree of certainty in the use of these agents which he had not found in the use of any other.

2. If the case is not seen sufficiently early to attempt the abortive plan, the next best is to carefully watch the symptoms, and persistently endeavor to carry the patient over, at the same time not forgetting that the disease will prove fatal in some cases.

There is one method worthy of particular mention under this head, and that has reference to rest during the inflammatory stage, by strapping the chest with adhesive plaster. It relieves pain, restrains cough, prevents exposure to air, allows of accurate physical examinations, in fact, renders them much more easily made, for the reason that the patient can change position without producing such annoying pain as would otherwise quite commonly be present. The temperature may be kept down by quinine or other means, and for the comfort of the patient, the physician may resort to such measures as his judgment may approve, having in view the conducting of the case to a successful issue.

DR. J. C. PETERS related his first experience in the treatment of pneumonia, in 1844, under the teaching of Schoenlein, of Berlin. His treatment consisted in the use of blood-letting, moderate in degree, and digitalis. These were frequently aided by alkalies, especially if a rheumatic element was present. Schoenlein placed great stress upon natural crises of the disease, and looked for crises by expectoration, skin, and urine, and unless he obtained these three points, he looked upon relapses as almost certain.

His success was great, but no greater than is to be obtained by other treatment.

His next experience was in Vienna, under Skoda, who adopted the expectant plan, and his success was very great.

At the same time he watched the treatment of Fleischman in the Homœopathic Hospital, in Vienna. In that hospital the patients had the most careful nursing, and again the success was very great. It was thought that the success was not so great, however, as that obtained by Skoda. But some of the recoveries seemed to border upon the marvellous, and some of the deaths were equally so.

His next experience was in the New York Hospital, where the cases were treated under the direction of Dr. Swett, and by the use of tartarized antimony, carried to vomiting and purging, which was kept up for about three days, and again the success obtained was very great. He had also seen the treatment by the use of small doses of tartar emetic, and with results equally as good as when large doses were used. He had seen the disease treated with aconite, but was not willing to say that this experience accorded with the extravagant statements of Ringer in the use of this article.

The treatment of pneumonia is not so simple as it was eight or ten years ago. A goodly number of cases apparently die from heart clot. A large number of cases are lost about the time of crises. He believed that if at that time the perspiration or urine became checked by the influence of cold, death quite commonly was the result, whereas, if the patient is kept warm and comfortable, he is far more likely to recover.

Dr. HUDSON presented statistics upon the mortality of pneumonia from 1804 to 1874, in which it was noticeable that there has been a steady increase in the ratio, independent of the increase in population.

The rate of mortality appeared much greater in some years than in others. In 1816, when the spotted fever was prevailing, there was no special influence upon the mortality of pneumonia. So, too, with regard to cholera in the years 1832, '49, '57, etc., the effect upon the population was not such as to render the mortality from pneumonia greater than it had been in previous years.

Dr. O'SULLIVAN mentioned the influence of cold as a predisposing cause among the laboring classes. He also referred to the influence of the poor sanitary condition of many of our school-houses as a predisposing cause, especially the condition of the closets. With regard to change of type he had noticed a considerable amount of debility and a tendency to delirium. His treatment was sustaining.

Dr. CARO adopted the sustaining treatment, and related his experience with the disease in the island of Sicily and this country. The subject was further discussed by Drs. Burke and Van Kleck.

MEDICAL BOARD OF THE EASTERN DISPENSARY, NEW YORK CITY.

Stated Meeting, January 14, 1875.

Dr. R. J. O'SULLIVAN, PRESIDENT, in the Chair.

DIPHThERIA: ITS CAUSES, CONTAGIOUSNESS, AND TREATMENT.

FEELING the practical importance of arriving at some definite conclusions relative to the causes, spread, and treatment of diphtheria, the Medical Board of the Eastern Dispensary, New York City, has held three meetings, which have been devoted to a discussion of this disease in all its phases. A mass of facts and records of cases have accumulated on the Secretary's books, too extensive for reproduction, therefore a brief outline only is attempted in this report.

Dr. R. B. PRESCOTT was sure that many cases reported as diphtheria are simply membranous sore throat, or cases of simple angina, where there may be considerable fever, and no swelling of the glands, but patches of exudations on the tonsils. In true diphtheria there is always extreme debility, and the disease may make its inroads very insidiously. He related a case of a Scotchman, in his practice, who complained for days of excessive weakness, pulse 135, pains in the back, no marked throat symptoms, in time swelling of the cervical glands, and finally paralysis of some of the involuntary muscles, and sudden death after a two weeks' illness. He regarded this as a case of constitutional diphtheria. While in the army, during the late war, something like one hundred cases of diphtheria appeared in his regiment after a long and fatiguing march. Stimulants and large doses of quinine were given to the soldiers, but some forty died. Upon the occasion of a recent visit to a village in New Hamp-

shire he found much alarm existing, owing to the appearance of diphtheria, scarlet fever, and other diseases in a large and new school, which the authorities had been obliged to close. The cause of this epidemic was directly traceable to the neglect of the janitor to keep the earth-closets in proper order. He had used sawdust in place of fresh earth. The case of a German, aged 20, who suffered for a number of days of excessive prostration and great difficulty of swallowing, was reported. The pulse was 100, temperature normal, and a careful examination of the throat revealed nothing abnormal. The patient died at last of apnoea. The post-mortem examination revealed nothing unnatural in lungs, heart, larynx, trachea, brain, medulla, and spinal cord, which was examined as low as the fifth cervical vertebra. There had been much diphtheria in the neighborhood, and a fatal case in the house where this German died. The treatment was sustaining and expectant. The presumption is, that this was a case of diphtheria blood-poisoning, with no marked local symptoms.

Dr. HENRY RAPHAEL had seen but a few cases of genuine diphtheria which were severe, judging from the sequelae, such as paralysis of the palate and strabismus. In one severe case, with all the usual symptoms, which made a good recovery, he resorted to cauterization, the use of the subsulphate of iron, inhalations of lime-water fumes, and carbolic acid, while from three to four grains of chlorate of iron and potassa were given every twenty-four hours. Strabismus appeared in three weeks after convalescence. In the case of a child, three years old, which recovered, the above treatment was pursued, and two to three grain doses of quinine were administered every two hours, and inhalations, from an atomizer, of the following mixture:

R

Carbolici acidi..... ʒ ij.
Ferri subsulphatas..... ʒ iv.
Aquæ calcis..... ʒ vi.

M.

Dr. M. S. BUTTLES, by invitation, read a paper on diphtheria, which he ranked with scarlatina and measles for contagiousness. He denied that this disease is produced by foul air, poorly ventilated rooms, insufficient food, etc., although these conditions may render the system more susceptible to the effects of contagion. It occurs in children from one to fifteen years of age. Nursing children are not apt to have it; never saw it in a patient over fifteen years of age. Bacteria rotunda, found posterior to the false membrane and in the blood, are the cause and result of diphtheria. Their presence on the mucous surface causes the exudation of membrane, in which they germinate. Entering the blood, and thrown off, or exhaled, they produce the same disease in others. He had no doubt that something floats in the atmosphere which causes this disease. Diphtheria is not so malignant where it makes its appearance in yellowish-white patches as when of a bluish-white color, having the character of a blister, appearing first in the posterior nares and descending to the tonsils, and perhaps to the trachea and bronchii. In this last variety the swelling of the lymphatics is first noticed, and upon examination the nares are found to be filled with the false membrane, which emits an offensive odor. If the membrane forms in the trachea or bronchii, the patient may die of blood-poisoning or asphyxia. In the treatment we should disinfect the blood, prevent the absorption and formation of more membrane, and support the system. Dr. Buttles has been in the habit of using Smith's solution of bromine, U. S. P., both locally and constitutionally. He applies

it in full strength to the membrane every two hours, until it is entirely destroyed, and administers it in doses of five to ten drops in water fully as often. The nose should be syringed freely with a weaker solution, if it is diseased. Quinine, iron, milk, beef-tea, etc., should be used. The patient should be isolated, the room freely ventilated and disinfected with carbolic acid. Under this treatment Dr. Buttle has lost but one case, and he has learned to regard diphtheria as comparatively harmless when absorption is prevented and the blood disinfected.

DR. ROBT. PRENTISS related the case of a child in Madison St., New York, which had measles, and afterwards diphtheria set in, complicated with diarrhoea, which proved fatal. Every house, for a block or two, had cases of scarlet fever, measles, or diphtheria, and the street gutters in front were reeking with filth! In cases of scarlet fever he had often noticed diphtheritic complications, with serious nervous depression. He had used, with benefit, inhalations of the fumes of lime-water through the medium of the spray. He mentioned the case of a child, six years old, which had suffered from diphtheria. In three weeks from convalescence paralysis of the heart ensued. Among the sequelae of diphtheria which he had noticed were blindness, paralysis of the muscles of the arm, paraplegia, and hemiplegia.

DR. JOHN P. GARRISH viewed diphtheria as of atmospheric origin, caused by the bacteria or other impurity which floats in the air. He looked upon it as a blood-poisoning, and doubted if it ever affected people in the full vigor of health. He knew the disease to be contagious, and would have the public authorities do all in their power to keep the air pure and the people in good health. To this end he deprecated the use of salt in the streets in winter, and said fresh straw should be placed in the street cars every day; that every child in the public schools should have a certain number of cubic feet of air, and that some means should be devised for the proper ventilation of tenement-houses. If people die from diphtheria, it is through neglect; and not more than one case in twenty reported as diphtheria is such in reality. He has no fear of the disease when properly treated. Was in the habit of giving his patients three grains of the chlorate of potassa, dry, upon the tongue, every two hours, with no drink for ten minutes. He also gave from three to five grains internally, every four hours. This for children. He urged the use of fresh milk, and favored the bromine treatment.

A lengthy discussion followed, participated in by Dr. Geo. V. Skiff, Dr. David Brecks, Dr. Fuller Walker, Dr. Gangert, Dr. Fluhurz and others.

DR. O'SULLIVAN remarked that it was not true, according to his experience, that diphtheria was easily cured. On the contrary, in very many cases no treatment whatever could do it. Despite the free administration of stimulants, and quinine in large doses, it was doubtful that local applications were useful in the earlier stages of the disease, beyond the cleansing of the affected parts; indeed he was convinced that in many cases it did mischief; however, in an advanced stage, when the blood-poisoning is being rapidly eliminated, and the deposit remains as a foreign body, blocking up the air-passages, and preventing sufficient nutrition at a time when it was most needed, local applications may be of service. Two such cases occurred in his practice, where eminent physicians had pronounced the cases hopeless. Local applications were made with the happiest results. The patients made subsequently a

rapid recovery. Errors in diagnosis should be guarded against by a thorough examination.

The horse-cars had been mentioned, from their crowded condition and ill ventilation, as a cause of propagating diphtheria. He was not prepared to affirm or deny this statement. It was probable that the exposure to colds, which were incidental to city-car travelling in the winter season, acted as a predisposing cause. He had seen on several occasions, on the east-side cars, small-pox patients on their way to and from the hospital. Indeed, the odor could be detected on entering these cars.

A great deal had been said for several years past concerning the unsanitary condition of tenement-houses, but their condition remains pretty much as it has ever been since the establishment of the Health Board. Defective drainage has been talked about until it may be said it has *drained off* all other mooted sanitary measures, and as yet no legislative action on this important subject had taken place.

The majority of the physicians participating in the discussion agreed on the following points: That diphtheria can be communicated from one person to another; that bacteria floats in the atmosphere; that certain unfavorable conditions, which lower the standard of health, as foul air, wet feet, etc., predispose an individual to take on the disease; that the apparently strongest, as well as weakest individuals, may have the disease; that there may be great constitutional disturbance without serious local throat affections; that dangerous sequelae may follow if the blood is not thoroughly disinfected; that, as a rule, an excessive use of stimulants is not good; that milk is a prime article of nourishment; that the disease should be treated both locally and constitutionally; that diphtheria, when taken in season, is easily controlled by proper remedial agents; that situation of house or town is no preventative against the disease; that many cases reported as diphtheria are not such, and that disinfectants should be largely used in the treatment of the disease.

At the conclusion of the discussion the following resolution was adopted:

Resolved, That diphtheria is contagious; that it should be treated on antiseptic and disinfectant principles, and that it can be controlled by proper medical treatment.

FULLER WALKER, M.D., *Secretary*.

Correspondence.

THE CHANGE OF PLACE OF MEETING OF THE STATE SOCIETY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your editorial on the last meeting of the State Society, you very properly, as many of the profession think, discuss the question of a change in the place as well as time of meeting. Will you allow me in behalf of some who are desirous that the meeting should be held where rational mental and bodily relaxation can be had in conjunction with scientific labor, to advance the claims of such places as Saratoga Springs, Lake George, and Niagara Falls, as against cities like Albany, Utica, Rochester, Buffalo, etc. At Saratoga, for example, the Society would have not only ample but unsurpassed hotel arrangements. The broad piazzas of Congress and Union Halls, the walks overshadowed by the leafy glory of June, the drive to the lake, would all invite and

secure social converse and brain rest. Besides, if we meet in any of the cities, there must always be a great strain upon the resident profession, not only to keep away from the calls of their patients, but to provide some kind of entertainment for those who are to a certain extent their guests. At Saratoga we should all be free from that sort of interruption and responsibility, and the Society, with ample and natural resources, would care for itself.

I am not sure, judging from the slight tinge of good-natured sarcasm in your remarks upon those who write upon "eye subjects," whether you would be inclined to attach much importance to the example of such societies as the American Ophthalmological and Otolological; but I may say that, after an experience of meeting in Boston and New York, we have found a meeting in Newport very much more satisfactory, and for the same reasons that have led me to suggest Saratoga as a very fitting place for the meeting of our State Society. The Albanians, of all others, as being those who have been most heavily taxed to receive us, would welcome a change which will make the meeting a place of enjoyment to them as to the others, instead of one of extra care and work.

I am, yours very respectfully,

D. B. ST. JOHN ROOSA.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from February 14th to February 20th, 1875.

BENTLEY, EDWIN, Assistant-Surgeon.—Granted leave of absence for one year. S. O. 28, A. G. O., February 16, 1875.

KNICKERBOCKER, B., Assistant-Surgeon.—Granted leave of absence for one month, on Surgeon's certificate of disability, with permission to leave the limits of the Department. S. O. 10, Department of the Columbia, January 30, 1875.

Medical Items and News.

SPECIALITIES IN MEDICINE.—Dr. Jacobi, Chairman of the Committee of the President's Address (State Medical Society), believing that our abstract of his report may convey a false impression, asks us to publish the following extract:—

"The general remarks of our President on the extinction of four hundred and fifty journals in the United States and Canada, and the unnecessary subdivision into specialities ought not to go unheeded. It is a matter of sincere congratulation on the part of all of us that those four hundred and fifty Journals died so early when there was no nerve-centre, no viability in them. Let us hope that many more of the same class will speedily fulfill their natural destination. We still have a large number of journals which express and contain nothing besides the desire of the editor or editors for notoriety, the title-page being the only original article, and the contents exhibiting the results of an active pair of scissors. Such publications, if they contrive to exist for any length of time, lower the tone of medical literature, demoralize particularly the younger members of the profession whose legitimate ambition and zeal is suppressed by beholding the facility with which noto-

riety is obtained, and diminish the chances of development on the part of better journals. This influence on the younger members of the profession ought not to be underrated. While they hope for success, they must look for the means of obtaining it. There are but few mortals whose ambition, both intellectual and moral, extends beyond the accomplishments and success of the best and most successful around them; but few who learn for the sake of knowledge, and work from inner necessity. Thus it is, that so many of them are blinded by the success of older specialists in the manner in which these became not only specialists, but noted and successful men. They are too apt to believe, that to be successful nothing is requisite but to be specialists. Therefore they are apt to rush into a speciality as soon as, or before, they graduate, neglect general medical knowledge, and miss their aim, both scientifically and pecuniarily, because they ignored the fact that their admired examples were medical men before they were specialists, and went, so to say, with a large capital, and all their mind, into a special business. It is true that the *progress of medicine depends on the continued efforts of specialists*. But those who have contributed most to the advancement of our science, were men who did not select a special work before mastering the domain of universal medicine, but selected it on the foundation of a general thorough education and knowledge. The brief remarks of the President, your Committee consider very timely indeed. While they do not disparage special studies and specialities of practice, they contain a wholesome warning against the heedless neglect of general medicine. Special journals, finally, while—when thoroughly scientific—they will not command a large sale, are *not only valuable but necessary*. Every worker needs them for study and reference. A practitioner may not require them for months, but now and then he wants to know about the chemistry and physiology of an old or new remedy of his—he turns to a journal on materia medica and therapeutics and is sure to find what he wants. He has an obscure case of nerve-disease, implicating the vaso-motor nerves—he turns to a journal (not such, however, as are published for the sake of notoriety and a large sale amongst laymen) on anatomy and physiology of the nerve-centres. Thus special journals may be, or either are, necessities for readers and writers alike, and constant sources of special information. *They are, when strictly scientific, the best indications of both the productive powers and the scientific needs of the medical men of a country.*"

THE ANNUAL DINNER OF THE ALUMNI ASSOCIATION of the College of Physicians and Surgeons, will take place at Delmonico's, on Tuesday evening, the 2d of March, at 7 P.M. A number of distinguished gentlemen have accepted invitations to be present, and interesting speeches may be expected.

PRESIDENT ELIOT ON PHYSICAL EDUCATION.—In his annual report President Eliot, of Harvard College, discusses the subject of the physical education of young men. While he does not recommend compulsory physical exercise at college, he thinks this should be part of every school education. "Most American schools," he says, "entirely neglect this very important part of their proper function; many young men, therefore, come to the university with undeveloped muscles, a bad carriage, and an impaired digestion, without skill in out-of-door games, and unable to ride, row, swim or shoot."

The liberal and progressive character of the government of the university is shown nowhere more clearly

than in its desire to promote the physical development of its students. The changes which have taken place during the past ten years in the character and variety of these exercises, and in the number of students who participate in them, is marvellous. For instance, to provide the greatest facilities for boating, a boat-house has been built by the corporation, so arranged that all students, for a very moderate sum, may indulge in this exercise for the season. The numerous athletic clubs which have of late years been formed, and the great variety of manly sports practised at Harvard, are abundant evidence of the success of this policy. The gymnasium has become far too small for the greatly increased number of students who frequent it, and it is now proposed to convert it into a swimming-bath which would be available at all seasons of the year.

DECLINE OF HOMŒOPATHY ABROAD.—"It is not to be wondered at that we now obtain few open accessions to our ranks; that the vacancies occasioned by deaths are scarcely filled up by new converts. Apparently homœopathy is almost at a standstill as regards professed adherents in this country. The Homœopathic Directory of this year contains few new names of practitioners that were not in the Directory of last year. Nor is it surprising that we have renegades.

"The paucity of recent conversions to homœopathy in other countries of Europe has been admitted and commented on by the homœopathic periodicals, and is, I think, satisfactorily accounted for by what I have stated."—*Dr. Dudgeon's Presidential Address at the British Homœopathic Congress.*

WHAT HAS VIVISECTION DONE FOR HUMANITY?—*The Br. Med. Jour.*, of January 9th, says: "Recent circumstances render it desirable that some attempt should be made to answer the question whether or not the practice of making experiments on living animals has materially aided the progress of medical science. To answer this question with completeness would involve an encyclopædic investigation of the sources and history of our present knowledge. It would be a work into which a great fund must be brought of patience, time, and labor. We shall, however, endeavor to present here at once and hastily, some leading data, such as may be gathered from a cursory review of the subject. We offer them as *mémoires pour servir*, and shall hope to be able to finish the picture by filling these rough outlines as time and circumstance will permit. We invite assistance and criticism from physicians, surgeons and physiologists. We present to-day a first contribution in the following skeleton sketch:

A. *It has succeeded in advancing our knowledge of physiology*, by 1. Discovery of the two classes of nerves, sensory and motor, by Sir Charles Bell. 2. Discovery of the functions (motor) of the *portio dura* of the seventh pair by Sir Charles Bell. Previously to this discovery, the *portio dura* was often cut by surgeons for the cure of neuralgia! 3. Discovery of the functions of the anterior and posterior roots of the spinal nerves by Sir Charles Bell. 4. Discovery of the functions of the anterior and posterior columns of the spinal cord by Sir Charles Bell and others. 5. Discovery of one of the functions of the cerebellum in co-ordinating muscular movements, by Flourens and others. 6. Discovery of the functions of the gray matter on the surface of the cerebral hemispheres as connected with sensation and volition, by Flourens, Magendie, etc. 7. Discovery of the motor functions of the gray matter covering certain convolutions in

the interior part of the cerebral hemispheres by Hitzig, Fritsch, Ferrier, Gudden and Nothmager. 8. Demonstration of the circulation of the blood by Harvey. 9. Measurement of the static force of the heart and discovery of other hydraulic phenomena, of the circulation by Stephen Hales, Ludwig, and others. 10. Discovery that atmospheric air is necessary to the maintenance of life, and that, when stupified by its withdrawal, animals may be resuscitated by readmitting it, by Robert Boyle, in 1670. 11. Discovery that atmospheric air by continued breathing becomes vitiated and unfit for respiration, by Boyle. 12. Discovery that the air was not only vitiated but also diminished in volume by the respiration of animals, by Mayon, in 1674. 13. Discovery of the relation, as regards respiration, between animal and vegetable life, by Priestly, in 1722. 14. Great discovery by Lavoisier on the physiology of respiration, from 1775 to 1780, namely, that respiration acts only on the respirable portion of the air, or oxygen, while the remainder, nitrogen, is entirely passive in the process; secondly, that when animals are confined in a limited space, they die when they have absorbed, or converted into carbonic acid, the greater part of the oxygen, and so reduced the air to the state of an irrespirable gas. 15. Numerous facts in the physiology of digestion observed by Blondlot, Schwann, Bernard, Lehmann, and others, by experiments on animals. 16. The discovery of the functions of the lacteals, by Colin, Bernard, Ludwig, and others. 17. The discovery of the functions of the right pair of nerves in relation to deglutition, phonation, respiration, and cardiac action, by John Reid, and others. 18. The discovery of the functions of the sympathetic system nerves, by Pourfourdu Petit, in 1727, Dupay in 1816, Brachet in 1837, John Reid, and Brown-Séquard. 19. The discovery of the phenomena of diastolic or reflex action, by Marshall Hall. 20. The discovery of the action of light on the retina, by Horngren, Dewar, and McKendrick. 21. The discovery of the glycogenic function of the liver, by Bernard Macdonnell, Pavy, etc. 22. The discoveries of the whole series of facts in the domain of electro-physiology, by Matteucci, Du Bois-Reymond, Pflüger and many others.

B. *In aiding Medicine and Surgery.*—1. The transfusion of blood, and introduction directly into blood of medicines; first proposed by Robert Boyle, in 1665. In 1665 Lewis transfused blood from vessels of one animal into those of another. First done in human beings by Dumis and Emmerts, in France, in 1666. Blundell's celebrated experiments on animals in 1818. Since done by many others—Dumas, Milne-Edwards, Dieffenbach, Bischoff, Doubleday, Brigham, Walter, Burton Brown, Klett, Lane, Lavy Bérard, etc. 2. Artificial respiration. Vesalius showed that by blowing up the lungs with air, after the chest was opened, stoppage of the heart's action might be delayed for some time. Hook, in 1664, first demonstrated the possibility of artificial respiration. Brodie, Hope, Le Gallois, Wilson, Philips, Marshall Hall and Silvester have practised it on human beings. 3. The cause of the cardiac sounds have been determined entirely by vivisectional experiments. 4. Phenomena of the circulation within the cranium examined experimentally by Kelly, Burrows, Reid, etc. 5. Hunter's operation for aneurism was first demonstrated and tried on living animals. This he did in 1785. He also found by experiments on animals, that in many cases the arterial coats were diseased immediately above the aneurism, and that consequently it was necessary, in order to avoid secondary hemorrhage, to place the ligature higher up. 6. The office of the periosteum in regen-

eration of bone, has been demonstrated experimentally by Dr. Haunel in 1740, Hunter in 1772, Lynn in 1837, Wagner in 1853, and Leopold Ollier in 1858. The practical importance of these observations is recognized by all surgeons who have had much to do with diseases of bones and joints. 7. The researches of Redfern into disease of cartilage. 8. The researches of Stricker, Cohnheim, Von Recklinghausen, and many others, on inflammation, more especially of the cornea and serous membranes. 9. Without vivisection experiments we would know almost nothing of the phenomena of inflammation. 10. Experimental inquiries into many zymotic diseases, showing occurrence of micrococci.

C. *In advancing Therapeutics, Relief of Pain, etc.*—1. Use of ether. 2. Use of chloroform. 3. Chloral discovered experimentally by Leibreich. 4. The action of all remedies are only definitely ascertained by experiments on animals. 5. Action of Calabar bean by Frazer. 6. Antagonism between active substances and the study of antidotes—many observers.

The above are simply examples which have readily occurred to the mind. To record all the facts given to physiology by experiments on animals, would simply be to write the history of the science. Therapeutics is yet in its infancy; but nearly all the facts definitely known regarding the actions of remedies have been gained by experiments on animals. To stop experiments on animals would as surely arrest the progress of physiology, pathology and therapeutics as an edict preventing the chemist from the use of the retort, test tubes, acids and alkalis would arrest the progress of chemistry.

THE TRIPLE FUNERAL.—One of the most remarkable events of the past week was the funeral, on the 16th inst., of the three brothers Delafield, who died almost simultaneously, of pneumonia contracted during the cold weather of that period. Joseph, the eldest, was eighty-five; Henry, eighty-three; and Edward, an obituary notice of whom appeared in our last issue, eighty-one years of age. Trinity Church was crowded, a large number of physicians being present.

TWEED.—DRS. J. R. Wood and Alonzo Clark were recently appointed a committee to examine into the physical condition of William M. Tweed and the treatment he is receiving in the penitentiary, and have advised that he be permitted to remain on duty as orderly in the hospital ward, and be treated as such.

DR. R. A. VANCE.—It is said that Dr. Reuben A. Vance, who had but recently been married, while absent in Pennsylvania, manifested symptoms of insanity, and while being brought home in charge of an officer managed, during the sleep of the latter, to obtain possession of his pistol and attempt self-destruction. At latest accounts the injury had not proved fatal.

A RAIL-CAR ACCIDENT.—The son of a well-known physician of the city was run over recently by a street car on Madison Avenue, and suffered the loss of his leg. The accident resulted from an attempt to get on the front platform while both the driver and conductor were inside the car. Sometime in April last the Board of Health made an effort to have the front platforms of our street cars closed by gates, so as to prevent access to or egress from them. Although the Legislature have granted them powers which are more nearly autocratic than anything which we have besides it in our government, the gates have never appeared, and the list of avoidable deaths and injuries from this cause goes on increasing.

AN OUTBREAK OF PUERPERAL FEVER.—The particulars of a recent outbreak of puerperal fever, at Wandsworth, near London, are given in *The Lancet*, of January 23, 1875. There were altogether ten cases, six of which had proved fatal at that date: five of these cases were attended by one midwife, and the sixth occurred in the practice of a medical man, and has been the subject of a coroner's inquest. These cases occurred in streets some distance apart, and their cause was attributed to the attendance of the midwife in question. The last fatal case was that of the wife of the physician mentioned. He had been called to see one of the midwife's cases, and shortly afterwards attended his wife in her confinement. Two days afterwards she had rigors, abdominal pains, etc., and died on the following day. An inquest was held to inquire if the deceased had had proper attendance, etc. This was most satisfactorily proved to have been the case, and a verdict of "death from natural causes" was returned by the jury. The writer in *The Lancet* says: "We must now inquire how it was that this woman was permitted to go from case to case, carrying infection with her for so long a period. We think it beyond all possibility of doubt that had she been stopped after the first case all the subsequent mortality and misery would have been prevented. The reason she escaped detection for so long a period appears to us to be as follows: She must have called on different medical men to certify the cause of death, and in no case, or perhaps only in one or two, was the death registered as puerperal fever. The Registrar-General, we all know, issues weekly a return of the deaths taking place in the metropolis, and is always careful to chronicle deaths from such causes as this. Had, therefore, the deaths been correctly registered, the public by this time would have been made aware of the existence of the fever through these weekly returns. We admit that there is some difficulty in a medical man, on being called in to an isolated case, committing himself at once to the statement that the case was one of puerperal fever, and believe that in many instances he would prefer to return the death as peritonitis, inflammation, thrombosis, etc. This difficulty and hesitation would cease if it were the law to hold an inquest in every case occurring in the practice of a midwife. In ordinary times such inquests would be few, but at times like the present, when puerperal fever is prevalent, it would be a considerable safeguard by sounding the note of alarm, and causing precautionary measures to be adopted.

EXTRAORDINARY FECUNDITY.—The Countess of Schlippenbach, of Heiligenkrew, in Croatia, was lately delivered of four infants at a birth—three girls and a boy.

A woman named Latouche, in Quebec, on the 10th of November last, had four boys at one birth.

REMARKS ON
SIMULATED AND HYSTERICAL LOSS
OF SIGHT.*

ILLUSTRATED BY CASES.

By D. B. ST. JOHN ROOSA, M.D.,

PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE UNIVERSITY
OF THE CITY OF NEW YORK. SURGEON TO THE MANHATTAN
EYE AND EAR HOSPITAL.

It is sometimes very difficult to draw the line between malingering and hysteria, for I suppose we all take it for granted that hysteria is a disease, and not simply a state in which diseases are absolutely feigned. Delicate girls and women, who have usually a diseased uterus or intestinal canal, readily and persistently complain of symptoms, to which an objective examination fails to find any foundation, and we are sometimes puzzled to know whether the abnormal condition of some organs and passages reflect a so-called functional disease, as really troublesome as an organic one, or whether it is a simple case of lying, for the purpose of exciting sympathy or attention. In the study of diseases of the eye our means of examination and conclusion, independently of the patient's statements, are perhaps as reliable as in any other part of our science, and yet there are some cases, even in ophthalmology, where the most exact examination of the choroid, retina, and optic nerve entrance, will not tell the actual amount of disease. At any rate, like all practitioners, we are sometimes called upon to discriminate between positive simulation without any motive—other than that of escaping some service or duty, such malingering as we see in soldiers or sailors, or in inmates of hospitals who have recovered from some malady, but who are unwilling to leave a comfortable hospital—and that form of simulation where, although the organ or organs complained of, are not morbidly affected to any considerable degree, the brain acts in such a morbid way that the patient exaggerates a slight disease or imagines a loss of function that does not really exist. During the last year my attention has been called to the not very infrequent cases of hysterical amblyopia, by two rather marked cases in my own practice, and one in that of my colleague, Dr. Agnew. They illustrate, I think, some rather interesting points in diagnosis and treatment, and I have therefore ventured to ask your attention to an outline of my own cases, with a passing allusion to that of Dr. Agnew's, and to a few remarks upon them.

The first case of which I wish to speak was, as was the second, that of a young woman, who suffered somewhat from dysmenorrhœa, and who was rather anæmic than otherwise. Thus, what are ordinarily supposed to be good foundations for hysteria were well laid.

Hysterical Amblyopia, with Concentric Limitation of the Visual Field.—Recovery.

Abbie X., æt. 7, a rather delicate-looking brunette, was advised to consult me by the family physician, in regard to the failure of her sight. The loss of sight was said to be so great that her father seriously considered the idea of sending her to an asylum where she might be educated as a blind person. The general health of the patient seemed to be fair, except that

menstruation was irregular and painful. The statement of the case as given by the young woman herself and by her father, was that, some months before, she had had an "inflammation of the eyes," and that since then, she had never fully recovered her eyesight; indeed of late it had failed very fast, until now, when she could just see to get about, but not to read or to sew. Her vision, as tested, by means of Snellen's test-types was, according to her own statement, $\frac{20}{200}$. The eye was examined by means of the ophthalmoscope, and absolutely no deviation from a normal fundus or from sound media was found. She was afterwards examined by a committee of the New York Ophthalmological Society, and they detected nothing to account for the alleged loss of sight, although an arterial pulsation was observed in one of the eyes. This arterial pulsation I was never able to see, nor were any of the surgeons of the Manhattan Eye and Ear Hospital, who examined the case. There was a hypermetropia of $\frac{1}{30}$, and when the patient's eyes were fully under the influence of atropine a positive glass of 36 inches focal distance caused her to say that her vision was $\frac{20}{200}$ instead of $\frac{20}{200}$. The visual field was concentrically limited to such an extent that when the head was 6' from the blackboard, and the eye was fixed upon the cross made for testing the field, the visual field was only about 3 inches in diameter. It is at once evident that a patient with such a small visual field as this one, and with so great a loss of vision, would have some difficulty in getting about alone, or would at least grope about somewhat. When I observed that besides the negative evidence of the ophthalmoscope, there were the facts that the patient not only did not grope about like a blind person, but that she was uncommonly active in getting about, and had no difficulty in seeing anything but printed type and sewing, the diagnosis was easily made. The patient had made up her mind to lie about all direct tests of vision, or she was actually self-deceived about her sight, but she had no notion that her vision could also be tested by her ease in getting up and down dark stairways, distinguishing the faces of visitors, and so forth. Although her father had brought her to my office with an idea that some operation would be necessary, or that she must go to a blind asylum, I informed him that his daughter would undoubtedly get well, and during all the time she was in the Manhattan Eye and Ear Hospital, until she recovered, about four weeks, she was treated, as I have reason to believe lunatics of a mild type are treated in well-regulated insane asylums. I found great difficulty in convincing her father that she would not become perfectly blind. Indeed, I have generally found that the friends and relatives of hysterical patients are the great bar to their getting well, and in the treatment of hysterical amblyopia at least, that it is well to have them completely beyond the chance of condoling with the patients. The treatment consisted in an attempt to improve the quality of the blood. She took iron, practised cold bathing, had exercise in the open air, while at the same time she was told that her eyes would gradually get well if she persevered in the prescribed treatment. Each week she was expected to read an additional line of Snellen's test-types, which she did, and on the 27th of October she was sent home, with an amount of vision expressed by the fraction $\frac{20}{30}$, that is to say, she could read $\frac{20}{30}$ fluently, and pick out some letters of $\frac{20}{30}$. Yet she persisted in saying that the visual field was the one she first admitted. Of course such a fact is perfectly inconsistent with the good vision she confessed to in reading type.

Although the main feature in this case was probably

* Read before the New York State Medical Society. 2.

malingering, there are others which cause me to class it among the hysterical cases. There was a motive for lying about her vision in the fact, that she was very anxious to learn to play on the piano, but as that privilege had been denied her, and she had found that a blind friend was learning this much-desired art in a blind asylum, she resolved to become blind that she might also become musical. But there was some hypermetropia, and enough to cause some trouble in reading or sewing for any length of time without glasses, and she had had an attack of inflammation of the eyes, probably catarrhal conjunctivitis. These two factors, with the disordered general condition dependent upon her dysmenorrhœa, probably caused the hysterical exaggeration as to her loss of vision. I am sorry to hear that since her dismissal from the hospital, the young woman, being surrounded by those who seem to prefer to believe her statements to those of her medical advisers, who have assured her relatives that she has no organic disease of the eyes, again declares that she is blind, and that there are serious thoughts of sending her to a blind asylum.

As is well known, we have ample tests for the detection of simulated complete amaurosis, especially when the patient claims that there is complete loss of sight in one eye; but I am not aware that we have any thoroughly good means of ascertaining whether a patient can see further than a certain line of Snellen's test-types, or whether the visual field is actually of the size that is claimed. It is true that Snellen states that malingersers stop short at a certain point, and deny that they can pick out even another letter, of whatever shape, from the next succeeding line; but this test, valuable as it is, will not always aid us to discriminate between actual and simulated loss of sight, so that our conclusions must be drawn from the objective examination of the eye with the ophthalmoscope, the general condition and the surroundings of the patient, the motives for simulation, and so forth.

The claim of the great diminution in the size of the visual field in this case was a puzzle to me, for a young woman who had not wit enough to see that an ability to get about everywhere with great ease, and to discern faces readily, was inconsistent with such a great loss of power to read type, would hardly be supposed to be so clever in dissimulation as to deny having a visual field large enough to prevent blind groping, and yet from the beginning to the end of the treatment persisted that it was ridiculously small. The detection of this kind of hysterical malingering, so far as I know, can only be had by a comparison with the other symptoms.

The second case of hysterical amblyopia to which I referred in the beginning of this paper, is one that I saw several times in consultation with Dr. Frank H. Rankin, one of the clinical assistants at the Manhattan Eye and Ear Hospital. I am indebted to him for the full notes, from which my outline is taken.

Conjunctival Congestion from a Scratch—Hysterical Amblyopia and Reduction of the Field of Vision—Dysmenorrhœa—Ooaritis—Recovery.

Maggie M., æt. 17, nurse. Previous to Jan., 1873, the patient never had any trouble with her eyes, and on that date the child she was taking care of scratched the ball of the left eye, about two lines from the cornea, on the nasal side; considerable pain and redness followed this scratch, which, however, subsided in a few days. In August of the same year the same eye became very much inflamed and exceedingly painful to the touch. This attack occurred while the

patient was at the sea-shore, and she attributed it to the glare of the sand. This period of inflammation lasted about a week, and occurred while she was menstruating. The week before Dec. 25, 1873, the left eye began to be painful, slightly congested, and to feel "very uncomfortable." The next day it suddenly became *very* painful, the vessels of the ocular conjunctiva very much congested, and the ball of the eye exceedingly sensitive to any touch. There was also profuse lachrymation.

These symptoms were related to Dr. Rankin on the afternoon of that day, when, without seeing the patient, he advised the instillation of a one grain solution of the sulphate of atropia four or five times a day. A saline cathartic and quinine were also prescribed.

Dr. Rankin saw the patient on Dec. 30th, 1873, for the first time. There was simply a slight amount of congestion of the ocular conjunctiva, and an occasional sharp twinge of pain was felt in the eye. The treatment by atropine was ordered to be continued.

Jan. 12th, 1874.—The patient has had but very little trouble with her eyes since the last date, except from cloudiness of the vision, which she has been led to attribute to the atropine, which she has used since the last note. The conjunctiva is clear; slight tenderness on moderate pressure upon the eye-ball. The tension seems to be increased. The ophthalmoscopic examination shows a large excavation of each optic papilla, but larger in the left than the right.

On the 15th of January I first saw the young woman, at the Manhattan Eye and Ear Hospital, in consultation with Dr. Rankin. Vision was found to be $\frac{20}{70}$ in the left eye, and $\frac{20}{40}$ in the right. There was some pain experienced in the eye, and it was tender, and the tension was increased. The excavation, although very large, was decided to be physiological, and it was supposed, although the ophthalmoscopic evidences were of a negative character, that we were dealing with a case of choroiditis.

Leeches were ordered, and the atropine was continued. On the 19th the pain continued, but was relieved for a time by atropine, the vision had sunk to $\frac{20}{200}$ (according to the patient's statement), and in the right eye to $\frac{20}{70}$. The field of vision was then examined and found to be very much diminished. The diminution was concentric and symmetrical, so that the diameter was not more than four inches, as tested in the usual manner before a blackboard.

The same treatment of leeching and the use of atropine was carried on until Jan. 22d, when the vision had sunk to $\frac{16}{200}$ with the left eye, and $\frac{20}{200}$ right. The visual field was also very small. The patient complains of much pain unless atropine is freely used. The tension of the globe seems to be increased, but neither the ophthalmoscopic appearances nor the patient's ability to go about alone gave any proof of such a loss of vision as that of which the patient complains. Jan. 23d, Drs. Agnew and Webster examined the case, and confirmed the facts noted of increased tension, large physiological excavation, and diminished field of vision. Dr. Agnew considered the case as somewhat obscure, but that it might be regarded as one of neuro-choroiditis.

The patient was seen by Dr. Rankin every day until Jan. 27th, when he found her in a severe attack of hysteria. Up to this time the notes show considerable variation in the visual power as stated by the patient. These variations serve to mark the functional nature of the disease, e.g., on Jan. 24th, it was $\frac{20}{20}$ in each eye, while on the 26th, it was claimed to be but $\frac{20}{200}$ in the right and $\frac{20}{70}$ in the left. The hysterical attack was evidenced by a state of apparent unconsciousness to

what was going on about her, while at the same time the patient was endeavoring to remove her clothing, etc., etc. She was ordered *decubitus*, beef-tea, wine; while tincture of valerianate of ammonia quieted the urgent symptoms.

Dr. Rankin now began, after this attack had passed away, the hypodermic use of the nitrate of strychnia, beginning with a $\frac{1}{100}$ th of a grain, under which she slowly recovered until Feb. 6th, when she had some nausea and vomiting and there was found to be some pain on pressure over the left ovary. The pressure caused nausea and a feeling of faintness. The patient had complained for a day or two before that she could not go down stairs without falling forward, while she could walk perfectly well on a level floor. A blister was applied over the left ovary, and a laxative followed.

On Feb. 11th, five days after, the nausea and vomiting still occur, and are sometimes preceded by a chill, followed by fever and sweating. The left eye is occasionally painful and red, but it is on the whole much better. The strychnia is now given up, and quinine and opium given. The dose of strychnia reached was $\frac{1}{100}$ th grain. Feb. 7th, the vomiting has occurred but once in the last six days, and there have been no chills. Vision is now $\frac{3}{8}$ in the left eye, + $\frac{3}{8}$ in the right, and the field of vision is nearly of the normal size.

On March 2d, the quinine having been continued up to this time, the patient was quite well, occasionally having a little pain in the left eye, which was always relieved by atropine; vision $\frac{2}{8}$ in each eye. Field of vision normal.

Subsequent inquiry showed that this patient always had marked tenderness over one ovary during menstruation, and that menstruation was always painful, and that after the slight injury to her eye it would flush up at each menstrual period. Besides this the first attack occurred during a menstrual period.

REMARKS.

I have no doubt that this young woman suffered some considerable pain in the eye, for its conjunctival congestion expressed that; but the exaggeration chiefly occurred in the answers as to her visual powers for letters and the visual size field. There was certainly a considerable amount of disease, although chiefly reflected.

In addition to the class of cases of hysterical amblyopia that I have attempted to delineate, there is another form that is not unfrequently seen, and one for which a few general remarks will suffice, without any account of particular cases. The hysterical ophthalmia in question is as apt to occur in males as in females, and is characterized by an amount of photobia, for which the condition of the eyes gives no warrant. Such patients come to our Eye Hospital, with their eyes not only bandaged but shaded, and over these protections sometimes blankets or shawls. Dr. Agnew saw one such patient, a young man, who had been kept in a dark room for nine years, and I have seen one who had been thus treated for two years. In neither of these cases was there any disease of the eye, except such a normal amount of photophobia that any one kept in a dungeon for a period of years would undoubtedly have.

The vague fear of amaurosis leads some sensible people to exclude eyes that show the least abnormal sensitiveness to light, from any illumination whatever. There is no chronic disease of the eyes that needs absolute exclusion from the light for but a few days or weeks at a time, and then under the direction of a physician; while acute cases will certainly soon

get from the bandage to the dark-colored spectacles. The tales we hear from patients, that they have been in dark rooms for months, are either exaggerated or show that they were under bad advice, and this advice is usually found to come not from physicians but from the laity.

The demoralized nervous system of these patients with hysterical retinal hyperaesthesia, is sometimes so hard to manage that it is difficult to remove the eye wraps and get them out of the darkness, and the physician will need first of all, to get such patients away from their sympathizing friends, and if he is at all doubtful as to the necessity for the seclusion of any case from daylight for a term of years, he may do well to reflect that a person might as well be struck blind at once from the entrance of light, as to drag out a miserable existence in a virtual prison, and at last die of constitutional disease.

Very many of our country villages have one or two persons, who, while in apparent health, have not got out of bed for years. These cases of hysterical paralysis, which render the subjects unable to go about, are analogous to those of hysterical photophobia, where the presence of the least light is so much dreaded.

Since reading the above paper, I am informed by Dr. Rankin that the patient is married and pregnant, and that she continues to have attacks of pain in the eyes,

AN EASY METHOD OF REMOVING ROUNDED FOREIGN BODIES FROM THE URETHRA

By E. L. KEYES, M.D.

I BRING the following case before the profession, because I believe the suggestion it contains to be one possibly of novelty, certainly of value. As to the origin of the idea of using Thompson's divulsor in lieu of forceps, for the extraction of a foreign body, it may be old, but if so the fact is not well known. Personally I certainly stumbled upon it, mainly by accident, but the excellence of the method and its extensive applicability were at once apparent to me, as they must be to any one who has had any considerable experience in attempts to extract foreign bodies from the urethra.

The best of the instruments in ordinary use for this purpose are the long urethral forceps, the crocodile forceps of Mathieu, or that of Collin & Cie., and the urethral scoop of Leroy d'Etiolles; but the first three of these are very apt to lacerate the urethra more or less, by pinching up a little of its mucous membrane along with the foreign body, or during the repeated and often fruitless efforts to seize the latter, while the last instrument named is apt to damage the urethra considerably by bruising its walls against the foreign body, which it extracts by forcing it along in front of its upturned extremity.

Only a short time before meeting the patient, whose history is about to be detailed, I saw another analogous case in consultation, where a smooth, round stone had been passed from the bladder and lodged in the urethra. It filled the canal completely, and although the forceps could be easily brought into contact with the anterior face of the stone, still it was found impossible to seize the latter, and after many fruitless attempts, in which considerable blood flowed from lacerations made in the mucous membrane, it was finally found necessary to incise the urethra in order to extract the stone. A fine probe was easily insinuated beyond the obstruction in this case, and nothing would have been easier

than to have followed a tunnelled divulsor over a guide past the stone, and to have thus extracted the latter, had the idea occurred to any one present, which it did not.

Other instances come to mind; but a self-evident fact requires no labored demonstration, and that a new and simple means of extracting foreign bodies from the urethra is a desideratum none will deny.

My case occurred at the end of August, 1874. Shortly afterward, while looking over a report read before the Georgia Medical Association, in April, 1874, by Dr. Westmoreland, Prof. of Surgery in the Atlanta Medical College, on "Thirty-seven Cases of Urinary Calculus" (*Atlanta Medical and Surgical Journal*, Oct., 1874, p. 415), I was surprised to notice that this gentleman had removed three small calculi from the urethra of a patient with Thompson's divulsor—introducing the instrument the first time, however, not with a view of removing the stones, but for the purpose, it seems, of dilating a stricture which detained them in the urethra. The case, in brief, was that of an old man, who had undergone external perineal urethrotomy for organic stricture at Dr. W.'s hands. The patient had before passed gravel, and continued to do so readily enough while he kept his stricture mechanically dilated. Discontinuing the use of his instrument, however, some gravel-stones came down and were arrested by the stricture. Stone could be felt through the integument, and was easily recognized by a sound passed through the stricture. For several weeks attempts were made to dilate the stricture so as to allow the stones to pass, but to no purpose. Finally, a Thompson's divulsor was introduced through the stricture, screwed open, and on being closed and removed, was found to have two gravel-stones between its blades. The doctor immediately reintroduced the instrument, opened it, and safely extracted another small stone.

Thus the priority in this manœuvre belongs to Dr. Westmoreland, or, perhaps, to another, although I have read of no similar case elsewhere. I adopted the same expedient, however, ignorant that it had been practised before.

My case needs no further comment beyond its report.

Dr. X—, 35, a practitioner in a neighboring town, married, and the father of healthy children, had renal colic five years ago, which terminated in sudden relief. He was not aware of passing any stone by the urethra. Three years and a half ago he had another similar attack, but could detect no stone in the urine voided. Two months before I saw the patient, he suddenly got retention without any previous diminution in the size of the stream of urine (he had never suffered from gonorrhœa). Retention lasted nine hours. A physician passed a catheter, but did not reach the bladder. On withdrawing the instrument the urine flowed spontaneously. Retention recurred with overflow, and relief was only obtained by again resorting to the catheter, although the latter again failed to enter the bladder.

During the two months there was continual trouble in urination. Sometimes the water would come in a small stream, more or less interrupted in a sudden manner, sometimes it would not flow at all for a time.

After seeing another physician, who diagnosed tight organic stricture, the doctor came to New York and consulted Dr. E. A. Maxwell, who passed a whalebone filiform guide into the bladder, felt the grit of the stone on its passage, and referred the patient to me.

I introduced a blunt steel sound down to the point of obstruction, at the triangular ligament, but not encountering any gritty feel, I concluded there was some

fleshy obstruction to the passage of any calculus the urethra might hold. I decided, therefore, that the latter must be stretched, and sent the patient home to prepare himself by an alkali, etc., for the operation. On the next day but one, he called at my office with Dr. Maxwell. I passed a whalebone guide readily into the bladder. It grated roughly along the stone during its passage. On attempting withdrawal, it was retained in the grasp of the urethral muscles pressed against the stone in that peculiar "bite" which is believed to be so characteristic of organic stricture.

A tunnelled divulsor was next easily passed over the guide into the bladder. It grated still more roughly past the stone. The instrument was screwed up to 20 (10 mm. diam.) without ether, and immediately unscrewed and withdrawn, containing the stone in its grasp as represented in the woodcut. The dimension of the calculus were $\frac{5}{16}$ inch long, $\frac{3}{16}$ diam., $\frac{3}{8}$ inch shorter circumference, $1\frac{1}{2}$ inch longer circumference. Weight 8 grains. Composition, oxalate of lime. Surface, very rough.

Entire relief followed the operation.

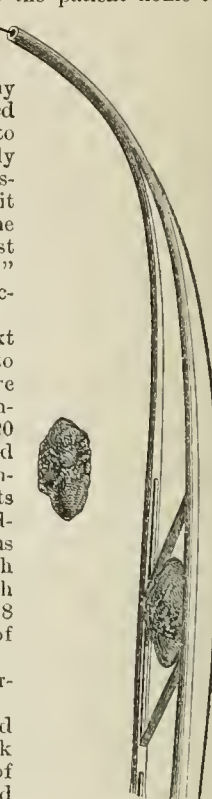

A full-sized blunt sound passed readily into the bladder one week subsequently, detecting a point of tenderness where the stone had been lodged, and causing the flow of a little blood, but not meeting any obstruction like a stricture. The patient remains well.

Although rough, the stone was rounded, and I think it probable that no rounded object in the urethra can escape slipping above or below the narrow blade of a divulsor, which happens to be pressing against it in dilating the canal, and finally becoming lodged between the two blades, and to be caught securely by them as they spring back on relaxing the screw; and this without any danger of the mucous membrane being pinched. It would be better if the divulsor used for extracting foreign bodies had but one cross-bar.

If the foreign body were a stone fragment impacted in the urethra after lithotripsy, it might have angles which would scratch the urethra during removal; but this objection would hold with more than equal force against any other form of forceps, for the blades of the divulsor shield the urethra very well.

Further trials of the tunnelled divulsor as a forceps for extracting foreign bodies from the urethra will soon establish its relative merits or defects as compared with other instruments. It promises excellently.

HONOR TO A PHYSICIAN.—Dr. Evan Pierce, J. P., County Coroner and five times Mayor of Denbigh, has lately been the recipient of an honor seldom accorded to living men. The foundation stone of a column to be erected in Denbigh by public subscription, in honor of Mr. Pierce, was laid. The column is to be ninety feet high, and is to be surmounted by a statue of the doctor. The cost of the whole being £1,000.

Stone, of natural size, showing position in which it was caught by the divulsor.

CASES FROM PRACTICE.

By J. G. PINKHAM, M.D.,

OF LYNN, MASS.

I. SECONDARY UMBILICAL HEMORRHAGE.

The child, a male, was quite vigorous at birth, and apparently sound in structure. The father was of scrofulous constitution. The mother was chlorotic in appearance, and had been for many years a victim of chronic uterine disease.

During the first few days of its life, the infant passed the meconium naturally, made water, and vomited slimy matter once or twice. It was never able to keep any kind of food on its stomach long. Its mother's milk, which it took with an apparent relish, would, in a short time be returned liquid, and of a bright yellow color. After the evacuation of the meconium, no passage from the bowels occurred worthy of being mentioned. Injections brought away nothing, and medicines were speedily ejected from the stomach. All the means used failed to arrest the vomiting. The skin gradually assumed a saffron hue. The cord came away naturally on or about the seventh day, and the navel healed perfectly. On the ninth day the nurse directed my attention to a little stain of blood on the navel. I took little notice of it, but ordered her to apply some tannin. This was done. The mother complained of the nurse for handling the child roughly, and thought she had injured it. Early the next morning the bleeding was discovered to be profuse, and I was sent for. I packed the umbilical depression with cotton-wool, soaked in a saturated solution of Monsel's salt, covering it with a compress and bandage. This controlled the hemorrhage at the time, but it soon recurred, and I reapplied the styptic with a like result. The third time I cauterized the bleeding surface, applied the styptic, and made pressure as before. Being obliged at this juncture to leave town, I gave directions for the nurse to keep careful watch, and if bleeding recurred to call another physician. It did recur, and the case fortunately fell into the hands of my friend Dr. Webster, who, recognizing the futility of the other methods that had been tried, applied the ligature, transfixing the end of the cord with two cambric needles, and tying beneath. I found on my return that there was still some oozing of blood, and reapplied the ligature. No more bleeding occurred, but the vomiting continued, the ejected matter becoming green like the feces which infants pass in certain conditions of gastro-intestinal disturbance. The child became much jaundiced, and wasted away, dying on the evening of the thirteenth day. Neither the ligature nor the needles had been disturbed.

Autopsy one hour after death, Dr. Webster assisting.

Body shrunken, yellow; abdomen hard, particularly in neighborhood of umbilicus. Bulging beneath the ligature. Parts above fetid. Cord unshrunken. Veins and arteries distended with a firm clot, reaching back to liver in vein, and to fundus of bladder in arteries. Blood effused into substance of cord, and beneath its sheath, extending laterally over abdominal walls from the deflection of the umbilical vein towards the liver. Peritoneal investment of small intestines, and mesentery intensely congested. Intestines below duodenum shrunken and nearly empty, but pervious. Moderate fecal accumulation in cæcum; colon looks like a whipcord. Stomach distended, with thin, green liquid like that vomited. Its mucous membrane apparently healthy. Duodenum partially distended. Its mucous membrane red, thickened, ulcerated. Mucous lining of jejunum and ileum reddened.

Gall-bladder and duct distended with bile. Biliary duct pervious. Right lobe of liver several times larger than left;* firm, yellow on section, mottled in portions, like the so-called nutmeg liver. Left lobe apparently healthy. Foramen ovale patent. Other viscera normal.

II. DISTENTION OF BLADDER MISTAKEN FOR ASCITES—SEVEN QUARTS OF URINE DISCHARGED AT ONE TIME THROUGH CATHETER.

I. A., aged 67, small in stature and thin in flesh. Family strongly predisposed to diseases of the brain and nervous system. About a year ago he injured his back while taking care of a sick person, and subsequently had more or less pain in that region, with a general failure of health. Several months before my attendance he began to be troubled with incontinence of urine, and a gradual enlargement of the abdomen, which his friends ascribed to an increasing obesity. The incontinence was not of long continuance. The first physician employed did not announce a diagnosis of the case, but gave vegetable diuretics and tonics, with the effect of aggravating the symptoms. The second was a female clairvoyant, whose manipulations were so vigorous and ineffectual for relief as to greatly disgust the patient. The third was an experienced and skilful physician, who pronounced the case one of ascites, and gave drastic cathartics and diuretics. The fourth was a miracle-worker, who directed his attention wholly to the head, rubbing it in such a way as to bring out a copious furuncular eruption.

I first saw the case on the 6th of April. The poor man was then suffering almost beyond endurance with distress and pain in back and abdomen. The latter was very prominent, as much so as we often see it in ascites, though with less fulness at the sides. He was passing an average quantity of urine, clear and non-albuminous; attempts at micturition frequent. Appetite poor. Tongue red and ulcerated. Bowels moved with great difficulty. During the night he was delirious and slept poorly. He gave evidences of failing brain power in deficiency of memory and general mental weakness. Frequent spasmodic twitchings of facial and other muscles. An examination of the abdomen showed plainly that the enlargement was due to liquid, and I was led to conclude that it might be a case of retained urine, rather than ascites, by the following circumstances:

1. The shape of the abdominal swelling was pyriform, something in appearance like that of a pregnant woman at the ninth month, the most projecting point being between the umbilicus and ensiform cartilage.

2. On palpation the fluid seemed less near the fingers than in ascites, the walls of the tumor felt thicker and firmer than those of the abdomen alone.

3. When the patient was turned on his side, the whole tumor fell over slightly, but there was no filling out of the loin as in ascites.

On attempting to verify or disprove my diagnosis by using the catheter, I found myself unable to pass the one from my pocket-case. The urethra was very irritable, the patient being thrown into nervous tremors and giving signs of pain as soon as the instrument entered the meatus. On my next visit I carried a series of gum-elastic catheters, but could not intro-

* At birth the difference in size between these two lobes of the liver is inconsiderable.—*Carpenter's Human Physiology*, page 797.

* For a thorough exposition of the subject of secondary umbilical hemorrhage, the reader is referred to an excellent article by Dr. Francis Minot, of Boston, published in the *American Journal of the Medical Sciences*, October, 1852, and to the elaborate report of Dr. Jenkins, of Yonkers, N. Y., to the American Medical Association in 1853. The latter may be found in the Transactions of the Association for that year.

duce even the smallest, so violent and continuous was the urethral spasm. Under ether, however, the spasm relaxed, and I introduced a No. 6 gum elastic, drawing off seven quarts of clear urine, the bladder not appearing to be fully emptied then. Subsequently I passed the same catheter without ether daily, the sensitiveness of the urethra gradually diminishing. The daily amount of urine was not less than two quarts. The effect of this evacuation of the bladder upon the patient's condition was marked. His appetite improved, and his nights became tranquil. The pain in the back nearly disappeared. He remained comparatively comfortable, though with a constant failure of strength, until his death on the 26th of April. No autopsy was made.

Remarks.—The great distention of the bladder in this case can only be understood by considering the length of time required for its development. Its starting-point was probably partial paralysis of the organ, leading to incomplete evacuation, and for a time to an involuntary overflow. The latter was stopped by the supervention of an irritable condition of the urethra, by reason of which spasmodic stricture occurred whenever the urine entered it. This stricture yielded only when the pressure from the accumulated urine became excessive, and was aided by the voluntary efforts of the patient, returning when a certain amount of urine had been voided. Thus through a series of months the bladder kept enlarging until it reached the capacity mentioned. The large amount of urine drawn from the patient daily after the first evacuation, was probably due to the fact that his diet was largely liquid.

III. DOUBLE ANEURISM OF AORTIC ARCH—DIAGNOSIS CONFIRMED BY AUTOPSY.

Mrs. B., aged forty-seven, housewife, came under my care on the 3d of Feb. last, suffering from a chronic malady, which was supposed by her friends to be consumption. She gave me the following history of her illness: She was naturally of a robust constitution and belonged to a healthy race. Four years ago she had an attack of "lung fever," so called by her physician, affecting the left side, and attended with rusty expectoration. Ever after that she was in delicate health, having at times cough and difficult breathing. About two years ago a small pulsating tumor appeared above the left clavicle, and at the same time her left arm was affected with a partial paralysis, numbness, pricking, and other abnormal sensations. The tumor gradually subsided, and the arm regained its natural condition, except that its pulse at the wrist was absent. Condition at date of first visit: Body fairly nourished. Appetite variable. Her most prominent symptoms were paroxysms of dyspnoea, with troublesome cough and expectoration. When the breathing was difficult there was marked stridor and the countenance became dusky in hue, and anxious in expression. Sputa often tinged with blood. Left radial pulse could not be found; right of fair strength; not notably changed in rate from the normal. Percussion revealed nothing abnormal in chest except slight dullness between second and third ribs on left side. Auscultation revealed abundant moist mucous râles on both sides, obscured somewhat during paroxysms of dyspnoea by the stridor. On right side of sternum, between second and third ribs, there can be heard a double murmur—modified heart-sounds—accompanied with a distinct thrill. Pulsation and thrill can be felt over the same space by the hand. With these signs and symptoms the diagnosis of thoracic aneurism, with chronic bronchitis, was easy.

The supposition of an obliterated aneurism on the left side, with a more recent one on the right, seemed necessary to a full explanation of her condition.

Treatment for chronic bronchitis nearly banished her cough, lessening also the frequency and severity of the dyspnoea. Various remedies were tried for the dyspnoea, but the tincture of stramonium in ten-drop doses, *pro re nata*, gave the most relief. About the 24th of March she took cold, as she thought, her cough returning, accompanied with profuse expectoration, and pain through right chest, shoulder, and arm. For one or two days the sputa was rusty, precisely as in pneumonia. The pulse was increased in rate, and the temperature moderately elevated. These symptoms partially subsided, but the dyspnoea progressively increased, causing great suffering until her death on the 31st of March.

Autopsy nine hours after death, Dr. S. S. Graves assisting. The result fully confirmed the diagnosis. There was an old aneurism of the arch on the left side just below the origin of the subclavian, passing upon the latter so as nearly to obliterate it; size, that of a turkey's egg. Interior consisted of concentric layers of fibrine, but partially decolorized, and readily separating. Symmetrically located on the right side, and of about the same size, was a recent aneurism, but few layers of fibrine having been deposited around its walls. Its cavity was loosely occupied by a fibrinous clot, nearly white, which sent a rope-like prolongation, some six inches in length into the heart, terminating in a ragged extremity, by which it was clinging to the valves, tendinous cords, and carneous columns. The lungs were perfectly healthy as far as could be discovered, except that one or two small patches on the free border of the right appeared collapsed. Bronchi not examined. Heart normal.

A CASE OF EPILEPSY (NIGHT FORM), TREATED WITH BROMIDE OF POTASSIUM, AND THE RESULTS.

By JAMES GILLIAM LA ROE, JR., M.D.,
GREENPOINT, L. I.

On the 1st of November last I was called to Miss R. J., aged about sixty. I found her very much prostrated, her pulse being 156, hardly perceptible, and semi-comatose as regards intellect.

On inquiry I learned that my patient was a life-long victim of epilepsy, and that for the last few years she had at least one fit a week, and very often two. They were of the *haut mal* form, occurring always at night. For the three nights preceding the day I was called she had had four fits. As a result her intellect was considerably clouded, and what history I obtained of her past life came from her relatives.

Stimulants were plainly indicated, so quin. sulph. gr. iij., and ammon. carbon gr. i., were given every three hours. Brandy, in the shape of milk-punch, was given in large doses during the day.

November 2d. Under the above treatment pulse fell to 108, with increasing vigor, both as to mind and body. Our patient answered questions put to her a little more readily than on the previous day, and complained of slight analgesia of lower limbs. This was the commencement of a series of hysterical phenomena, which subsequently proved very alarming to her friends.

November 3d. Increased hysterical symptoms exhibited themselves in shortness of breath, *globus hystericus*, and nervous twitchings of the muscles in dif-

ferent parts of the body. Just before I made my visit she called her friends to her bedside, and bade them all good-by, declaring that the time for her exit from this world was at hand. On examination her pulse was found to be 96, and pretty strong. The tonic and stimulant plan had been kept up unremittingly, doing noble duty, save for the fact of promoting hysterical symptoms, which, as intimated before, grew very alarming to her friends. I was implored to relieve them, and thereby found myself in a quandary. A few years ago, and not very many either, there came a time in my life which comes to all would-be graduates sooner or later. I refer to the writing of that all-important article yeletpa "Thesis." Mine was on "Bromide of Potassium," and with no experience to guide me I could merely echo the words of my teachers. I refer to two sentences particularly. In speaking of the use of the drug in epilepsy, I wrote:

"From its effect of producing anemia of the brain we can readily perceive how useful it would prove in the day form of epilepsy, where there is marked congestion. Of course it would be suicidal to give it in the night form, wherein the condition of the brain is anemic."

I had for my authorities Profs. Flint and Hammond, Roberts, of London, in his "Practice of Medicine," is clearly of that opinion. Hence my quandary. But there was no time for delay, and as the patient had been treated very lately without effect, I concluded to yield to the desires of her friends and address my remedy to the hysterical condition alone. I then ordered 40 grains of the "bromide of potassium" to be given every three hours, and this alone.

November 4th. Patient much quieter this morning. Had a good night's sleep. In order that the hysterical symptoms might not return, the drug was ordered continued. Pulse 84.

November 5th. Everything progressing finely.

November 6th. I made my last consecutive visit, and, by way of experiment, ordered the drug to be given until a rapid return of the epilepsy would call for its withdrawal; to be given three times a day instead of every three hours.

On the night of December 19th, about seven weeks after her last fit, Miss R. J. had another. There could be no mistake, for her friends heard the usual cry and the pillow was found to be bloody. An examination of the tongue showed considerable laceration.

Considering that quite a victory had been gained, I ordered the "bromide of potassium" to be continued. Up to date there has been no subsequent fit. Her friends notice a brighter intellect also. Should another fit occur shortly, and there would be nothing strange in such an event, I shall order the drug to be given in drachm doses three times a day, and so on *ad libitum*.

In conclusion, I would state that this communication is claimed to be in nowise original. It is merely given as a matter of clinical record. Without doubt other physicians have proven the theories advanced by the different authorities to be incorrect in the premises, and so have acted accordingly. Admitting this, additional evidence can surely do no harm.

107 HURON ST., Jan. 25, 1875.

MR. HOLLOWAY, of pill and ointment notoriety, is reported to have purchased an estate with a view to establishing a college for women which will be capable of accommodating four hundred. The grounds have cost £25,000 and the cost of the building is estimated at £175,000.

Progress of Medical Science.

THE ANTAGONISM BETWEEN MEDICINES.—The following extracts are taken from a report of a committee of the British Med. Association, detailed to investigate the antagonism of medicines, by J. Hughes Bennett, M.D., chairman.

Sulphate of Atropia and Meconate of Morphia.—In this investigation eighty-one experiments were performed on rabbits and dogs. The experiments on rabbits were summed up as follows:

1. Sulphate of atropia is physiologically antagonistic to meconate of morphia, within a limited area.

2. Meconate of morphia does not act beneficially after a large dose of sulphate of atropia, for in these cases the tendency to death is greater than if a larger dose of either substance had been given alone.

3. Meconate of morphia is not specifically antagonistic to the action of sulphate of atropia on the vaso-inhibitory nerves of the heart.

4. The beneficial action of sulphate of atropia in cases of poisoning by meconate of morphia is probably attributable to the action which the former substance possesses of contracting the blood-vessels, and thus diminishing the tendency to cerebral and spinal congestion produced by salts of morphia.

The experiments on dogs showed that sulphate of atropia modifies the physiological action of meconate of morphia, and may even save life after a fatal dose of the latter. The limit, however, is so narrow as to be of no practical value.

Tea, Coffee, Theine, Caffeine, Guanine, on the one hand, and Meconate of Morphia on the other.—In this investigation one hundred and seventeen experiments were performed.

1. Theine is antagonistic to meconate of morphia inasmuch as the action of the one substance modifies that of the other, and may even save life from a fatal dose of either substance.

2. Meconate of morphia delayed the appearance of the convulsions characteristic of the action of theine; but, on the other hand, theine, if given in large doses, did not affect in a marked degree the action of meconate of morphia, because symptoms of poisoning by theine were soon manifested.

3. Further experiments on cats showed that (a) while a cat may recover from the effects of a dose of 1½ grains of meconate of morphia given alone, it will not recover from the effects of a dose of 2 grains, even although the effects of the latter dose are modified by those following the introduction of 4 or 5 grains of theine; (b) that in three cases the animals recovered from the effects of 1½ grains of meconate of morphia and 4 to 5 grains of theine, while they died when the same dose of meconate of morphia was administered eight days afterwards; (c) that, when the dose of theine was increased beyond 5 grains, the animals invariably died, apparently from the effects of theine.

4. Experiments on rabbits, as to the antagonism between meconate of morphia and theine, were found to be unsatisfactory as regards the purposes of this inquiry, because both drugs produced epileptiform convulsions in these animals.

5. The results obtained in investigating the action of caffeine and guanine as antagonists to meconate of morphia were similar to those observed with reference to theine.

6. Experiments were made on dogs to ascertain the effects of strong infusions of tea and decoctions

of coffee as antagonists to meconate of morphia. These were unsatisfactory, chiefly because the tea or coffee was usually vomited so soon as to prevent the possibility of the exercise of any physiological antagonism. At the same time it was observed in several instances that the administration of tea or coffee so excited the animals as to prevent them from falling into stupor or coma after a dose of meconate of morphia, which would have produced this effect had the tea or coffee not been given.—*British Med. Journal*, Jan. 23, 1875.

CASE ILLUSTRATING THE VALUE OF EXTERNAL EXAMINATION IN MIDWIFERY.—The patient whose history is here related was 27 years of age, and had been confined three times previously, losing much blood at each confinement, and suffering during the last one from excessive flooding. Dr. Giles, the physician who reported the case, was called to see her early in the morning, after she had been in labor about six hours. The pains were frequent but not efficient, and he observed that she was much larger than most women are at term. The os was found high up, the size of a florin, and dilatable. The presenting part did not engage; it had the shape of the cranium, but felt soft like the breech. A hand or foot could also be felt. The vulva and vagina were œdematous, and there was a semi-elastic swelling, the size of a walnut, on the floor of the vagina. On external examination the fetal heart was found beating about two inches below the navel, and to the left of the median line. To decide as to whether there was more than one child, the doctor resorted to palpation through the abdominal walls, by which he satisfied himself that there was but one, and he also made out that the position was either the second or fourth cranial. After an hour he applied a binder and ruptured the membranes. He then found a second bag of waters, and a fourth position, complicated by a presentation of the left hand. Holding the hand back during four pains, it then remained above the head. A great deal of liquor amnii escaped with each pain; the head did not advance, and the vaginal tumor increased. Later, the head was found to have receded. He therefore applied Barnes's forceps, and easily brought down the head until it reached the tumor. This he divided with a knife, and turned out a clot. The slight hemorrhage was easily checked by pressure of the finger, and the delivery of the head completed with the forceps. The subsequent history of the case presented no features of special interest, and the patient made a good recovery. The points of interest, in the reporter's opinion, were: 1st. The existence of two distinct bags of water, which was verified on examination of the placenta, and which caused doubt at first as to the particular presentation. 2d. The value of external examination in removing this doubt. 3d. That it was good practice to incise the tumor and turn out the clots, instead of waiting for its rupture by the descending head.—*Obstet. Journ. of Gt. Brit. and Ire.*, January, 1875.

TREATMENT OF CERTAIN TUMORS BY THE SUBCUTANEOUS INJECTION OF ALCOHOL.—Schwalbe, of Weinheim, has reported one hundred cases of various forms of indolent glandular swellings treated successfully by the subcutaneous injection of the tincture of iodine. Latterly he has used injections of simple alcohol in fifty similar cases, and has found the results equally favorable, and the time required for a cure no greater, and he therefore concludes that the alcohol is the essential remedial agent. He explains its curative action as follows: It establishes a state of chronic in-

flammation in the connective tissue, causing it to contract by degrees, and thus pressure is brought upon the vessels and the lymphatics are obliterated. These effects, and the consequent hardening of the connective tissue, he proposes to utilize in the treatment of other tumors, and he reports the cure of fatty tumors by the use of such injections, to which some ether was added in order to dissolve the fat. He finds, however, the most important application of his plan in the treatment of cancer, by preventing its extension to the neighboring tissues and lymphatic glands. The tumor is first to be isolated, as it were, by causing the connective tissue on all sides of it to become shrivelled; then, the contracting connective tissue, approaching the growth itself, presses upon it, cuts off its blood supply, and so causes it to disappear by atrophy. Lymphatic glands which are already affected are to be similarly treated. Schwalbe, with Dr. Hasse, claims to have cured three cases of cancer of the breast in this way.—*Sitzungsbericht der niederrhein. Gesellschaft in Bonn*, 1874.—*Allg. med. Central Ztg.*, Jan. 23, 1875.

INDICATIONS FOR ARTIFICIAL RUPTURE OF THE MEMBRANES.—The following conclusions are drawn by Hugenberger, of Moscow, from a careful analysis of the cases in which this procedure was adopted in 10,482 confinements occurring at the St. Petersburg Lying-in Hospital. He considers that the early rupture of the membranes is to be recommended as a powerful oxtocic agency, except in cases of hemorrhage, and advises the practice of it even when the os uteri has opened no more than one and a half finger's breadths. He believes that this rule is applicable in the following cases: (1) With multiparous women, especially such as have been pregnant more than three times, if the dilatation of the os is not retarded by feeble pains; (2) in primiparæ generally, where the pains are normal but the os dilates too slowly, and the membranes remain for a considerable time tightly drawn over the head, without intervening fluid; (3) if the presenting head does not adapt itself to the pelvic inlet, though the pains are regular and the pelvis normal, the uterus continuing soft and not forcibly contracting upon the child's body; (4) where the liquor amnii is abundant, the lower portion of the uterus broad and soft, and the fœtus presents by one or other extremity, but does not promptly engage in the inlet. Prolapse of the cord or of the extremities should be carefully guarded against, and to avoid such an accident, it is advised that the woman be placed on her side while the membranes are broken, and then that light pressure be made on the fundus, so as to force the presenting part towards the inlet. The same object may be accomplished by puncturing the membranes with a sound at a higher level, by which the liquor amnii will drain off; (5) when, in case of twins, with a longitudinal presentation of the first one, there is inertia of the uterus from excessive distention and the dilatation of the os ceases; (6) when the labor is thus delayed in case of a dead fœtus. On the other hand, early rupture of the membranes is contraindicated in excessive and convulsive pains, in case of resistance of the soft parts, where the os is rigid, unyielding, and turgid; in transverse presentations, and those of the face and forehead; in the so called posterior chîa and occiput positions of the fœtus; in contracted pelvis, when the lips of the os uteri are lax and dependent, and when the soft parts are not distended by the liquor amnii; in case of pressure upon the superior portion of the cervix by large parts of the child, and finally, when the cervix is caught between the child and the anterior wall of the pelvis.—*St. Petersb. med. Zeitscher.—Memorabilien*, 6, 1874.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 6, 1875.

THE UTILITY OF MEDICAL LEGISLATION.

THERE is a great deal of difference of opinion in regard to the utility of legislation on medicine. Not so much as there has been in times gone by, it is true, but still enough to give the subject a very unsettled aspect. If we attempted to interpret professional sentiment in regard to matters of legislation in general, we believe we should count a large majority on the side of the opposition. Those who have faithfully studied the effect of laws enacted either for the benefit of the community, or for the benefit of the profession, are pretty thoroughly convinced that, far from making any tangible progress towards much-needed reforms, we have taken very many backward steps.

The history of the labors of the State Society in such a direction is a melancholy proof of the truth of the assertion, and its efforts to shake itself entirely from any dependence upon the Legislature, carries with it a moral which should not be unheeded by other organizations, who are more or less sanguine of the good results of prospective laws regulating the practice of physic in the different States. Several bills having the latter object in view are before the different Legislatures, and although they are all intended to protect the community against quackery, are in the main judiciously framed, we cannot resist the conviction that if they pass at all, most, if not all of them, will be practically inoperative.

Setting aside the strong probability that the acts will be constantly subject to repeal, and to the incorporation of modifications more ruinous to our interests, than if we had no legal enactments at all, we can hardly expect to be in a position to enforce the provisions of the bills, or to mete out justice to offenders. In all our efforts to regulate the practice of medicine, we place ourselves in a very anomalous position towards the community. We take every pains and use every effort to protect the people against the evils

of quackery, oftentimes against their will, and then shoulder ourselves with the responsibilities of enforcing the law afterwards. Evidently there is very little, if any, sympathy exercised towards us in such endeavors by the very people for whose benefit the law was originally framed. As far as we ourselves are concerned, the task is not only a thankless one, but is in its ultimate results so far from being satisfactory, that it tends to dishearten the most enthusiastic committee, or to render nugatory the best directed labors of the most faithful and conscientious board of examiners.

In the case of the present law now in operation throughout this State we have an example. As a law, it virtually, so far as any good results to legitimate practice is concerned, amounts to nothing. The censors of the County Societies are empowered to summon all those who have no diplomas or licences to appear before them for examination. Unless these men pass an examination before these boards they have no legal right to practice. But it must be recollected, that this law gives the same privileges to eclectic and homoeopathic societies, the members of which are legally entitled to practice the dogmas of their respective schools. If an applicant fails to pass one board of censors, there is nothing to hinder him from applying to the others. In fact, this is repeatedly done, and a special bid is made for these examinations by the eclectics, who openly advertise for all who may have been rejected by the other boards. If any of the lame ones fail in spite of these splendid offers to succeed, it is their own fault, and not that of the obliging board of "eclectic" examiners.

This is the case when, on the part of the censors of the County Societies, every means is taken to give impartial examination, and thus to carry out the letter and spirit of the law. When we reflect that all this labor is gratuitous, that the time of some of our best and busiest men is taken up by any one who chooses to apply for an examination, we cannot help thinking that we have taken upon ourselves a very thankless task.

Not only do we work hard to enforce the law, but we are expected also to defend encroachments upon it, as if the said law was for our benefit alone. If a malcontented and defeated candidate chooses to practice, in spite of the protest of the censors, who is to bear the burden of a lawsuit? The community quiet their consciences in regard to this matter by assuming that it is no more than right that those who are so specially interested in the law should be the ones who should discharge this responsibility. As it is with the law of our State, so it will be with the similar laws in other States. If we wish to accomplish anything we must do it ourselves, and even then we are pretty sure to fail.

The whole difficulty in making the different laws effective rests in a proper want of understanding on the part of the community. We can never expect to accomplish anything until we convince the people

that these laws are intended more for their protection than ours. A learned profession should be above making any requests for legislative acts to benefit itself. If it cannot stand on its own merits, it has no claim whatever even to ordinary respect. Any effort to force such a consideration by a legal enactment is not only absurd, but positively ruinous. Our office is to protect the people as much as possible against quackery. If the community do not care to properly interpret these intentions, that is no concern of ours. Practically speaking, the people are not prepared to appreciate our motives, and will never be, until they are sufficiently educated to draw the line between quackery and legitimate medicine. When that time comes, there will be no difficulty in having suitable laws passed, and the people will themselves take the proper steps to punish any offenders.

If we must legislate at all, let it be in the direction of improving ourselves. There is a great deal that can be done in this direction. Our college regulations can be made more stringent, our standard of preliminary requirements raised, our terms of study extended, and, in fact, the whole system of medical education can be remodelled. By restricting our efforts to such reforms, we can at least prevent quacks and incompetent persons from coming into our own ranks, and this should satisfy us for the present.

OUR COMMENCEMENTS.

THE Medical Colleges in New York have graduated a larger number of students than ever before, and it is the uniform testimony of the professors that the examinations were very creditable. On looking over the catalogues it is very encouraging to notice the increased proportion of those who have the degree of Bachelor of Arts. This is certainly a subject for congratulation, and speaks well for the future medical man. New York, too, has proved itself entitled to the reputation of the centre for medical teaching. The Commencements, instead of being the occasions of a dry lecture and the presentation of diplomas, are now made attractive by addresses from eminent speakers, fine music, and all the other pleasant accessories which go to make up first-class entertainments. The awarding of numerous prizes is also a notable feature, and is no mean incentive to extra diligence on the part of the students.

PHILADELPHIA MEDICAL SCHOOLS.—A correspondent of the *Med. and Surg. Jour.*, says that the faculty of the University, still lacking funds for the completion of their plans, are making an effort to obtain an additional grant from the Legislature of \$125,000, and promise to raise a like movement by subscriptions. The Jefferson College subscription fund has already reached \$100,000, which entitles the college to an equal sum from the State. No movement, so far as is known, has been made as yet by the latter school, toward an application of the fund.

Reports of Societies.

NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

Adjourned Stated Meeting, February 2, 1875.

The President, DR. MEREDITH CLYMER, in the Chair.

The special order was a paper on "Partial Paralysis and Want of Coördination from Irritation of the Genital Organs," by Dr. LEWIS A. SAYRE.

DR. SAYRE referred to a paper "On Reflex Paralysis, caused by Congenital Phymosis and Adherent Prepuce," which he had presented to the American Medical Association in 1870. He read extracts from letters received from Mr. Barwell, of London, Dr. Pitcher, of Detroit, and others, confirming the views therein set forth, and relating similar cases coming under their observation, but the nature of which, until then, they had not understood. So many like cases, he said, had since then come under his notice, that he thought it proper to bring the subject again before the profession more fully, as he was satisfied there were many grave affections of the nervous system attributable to this cause, whose nature has not as yet been suspected. He had no theory of explanation to offer; and he hoped that some light might be thrown on the subject by the members of the Society. It had seemed to him that in many cases an anemic condition of the spinal cord obtains, as some of the patients lose entire muscular power, even the power of speech, in the erect posture, and yet, lying on the back for a little time, they recover the power of speech and motion.

Eight cases were then related among both sexes, illustrating the peculiar effects of continued irritation of the genital organs, such as retention of urine, general motorial paralysis, paraplegia, complete and partial, paralysis of the special senses, spasms, clonic and tonic, idiocy, etc., etc. The most marked peculiarity of all these cases has been that almost immediate improvement, without any mechanical contrivance to correct the deformity, on relieving the genital irritation, would happen directly; decided improvement would sometimes be noticed within twenty-four hours, and in most, complete recovery in the course of a few days.

And in view of the absence of those members of the Society who were best able to discuss this interesting question, as well as to make further case contributions, he would suggest that the discussion on the paper be made the order at a subsequent meeting. He had not himself seen cases similar to those mentioned by Dr. Sayre, but he had, since his attention had been first called to the subject, some twenty years since, seen a great variety of nervous troubles, both of motility and sensation, unquestionably ascribable to continued irritation of some one of the genital organs, and that in both sexes, and at all ages. Many persons had been sent to him for treatment, suffering from more or less loss of motor power, and with increased, lessened or perverted sensation, supposed to be from some disease of the nerve-centres, in which he had found the origin of the symptoms either in the urethra, bladder, uterus, ovaries, or external genital organs of the female. On the removal of the local trouble, the nervous troubles disappeared without special treatment. In stricture of the urethra this was a frequent state of things. He had seen many cases

which had been treated for diseases of the spinal cord unsuccessfully for a long time, in which the paresis and anaesthesia—a hyperaesthesia—disappeared as soon as the stricture was cured.

With regard to the nature of the disease, Dr. Sayre had said that he had no theory to maintain: he was not prepared to say whether there was anaemia or hyperaemia of the cord. Now he (Dr. Clymer) had serious doubts whether the morbid expressions were due to either condition. That either one or the other existed there was no proof; and there was much in favor of a belief that the vascular system of the cord and its coverings was not concerned, or if so, only secondarily. He believed that the present tendency to implicate the circulation of the cord or brain, or their membranes, in the pathogeny of so many of the functional diseases of the nervous system was an error. He thought that in such cases the nerve-cells, sensory and motory, were themselves in fault; that the irritation impinged directly on them. He thought in the class of cases just mentioned by Dr. Sayre, this was shown by the rapidity of the disappearance of the nervous troubles after the peripheral irritation had been removed.

After some remarks by Dr. Farnham and others, the discussion was adjourned to March 15th.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Feb. 10, 1875.

DR. F. DELAFIELD, PRESIDENT, in the Chair.

POISONING BY ACONITE—TEMPORARY BRIGHT'S KIDNEY.

DR. BLAKE related the case of a lady who had been poisoned by aconite. She drank about a drachm of the tincture mixed with equal parts of chloroform. The characteristic symptoms of the poison came on in the course of half an hour, notwithstanding the greater part of the contents of the stomach had been evacuated by the use of the stomach pump within fifteen minutes after the accident. She soon became insensible, and the pulse and respiration ceased. Life was maintained for three hours by the use of a powerful battery, and by the employment of oxygen gas in equal parts with common air. At the end of three hours there was a faint perception of the pulse. The prolonged effect of the poison upon the action of the heart was quite remarkable, but an explanation was seemingly offered for such a phenomena by the condition of the urine. That secretion was found loaded with albumen and contained fragments of casts. This condition of things was thought by several gentlemen to indicate a chronic disease of the kidney and to increase the gravity of the prognosis. An examination of a second specimen of urine presented the same appearances. After this, however, the most careful examination of the secretion failed to discover anything abnormal. The patient recovered, and at the time of reporting the case, it was a week and a day after the poison had been taken.

The interesting question which presented itself had reference to the possibility of the kidney trouble being merely temporary, occasioned by the irritating effects of the poison. This possibility was strengthened by the fact that the skin was profoundly impressed, there being a static congestion of its surface and the cuticle peeling off on being rubbed.

DR. DELAFIELD concurred in this opinion.

MALIGNANT DISEASE OF THE OESOPHAGUS.

DR. E. MASON exhibited a specimen of malignant

disease of the oesophagus producing stricture of that organ. It was removed from a male mulatto, aged fifty-three, and of intemperate habits. Dr. M. was called to see this patient in the Colored Home in the early part of October. He had always enjoyed good health until two months before his admission, when he commenced to lose strength and flesh very rapidly. Two weeks before that period he first noticed a difficulty in swallowing solid food, and at times it was impossible to swallow liquids. He located the obstruction in the neighborhood of the top of the sternum. At the time of his admission, when he attempted to swallow liquids, they would become arrested, the pharynx would become distended for a moment, and then the whole quantity would be regurgitated by a gagging movement.

Dr. Mason succeeded in passing a flexible, tapering bougie (scale 18), and eight inches from the beak an obstruction was met. After manipulating for a while, the instrument deviated a little to the right, and finally passed the stricture. After this an oesophageal bougie was passed into the stomach. On the withdrawal of this instrument a small quantity of frothy blood followed.

This bougie was passed once or twice a week for two or three weeks, until a No. 6 oesophageal could be used. Having apparently improved, it was determined to see if he could not swallow some solids, and at the suggestion of Dr. Thebaud, some raw oysters were given to the patient. He only succeeded in swallowing one or two of these, the remainder being returned. His strength failed rapidly after this, and he died very quietly and without pain on Nov. 22.

At the autopsy there was found a fusiform bulging of the oesophagus beginning two inches above the stomach, extending upwards four and a half inches to within six inches of the epiglottis. The circumference of this enlargement over its middle portion was five and a quarter inches. Upon section, an irregular mass was seen projecting into the oesophagus from an attachment about four inches in length, upon the posterior and left lateral walls. This mass was irregularly lobulated and rolled upon itself longitudinally, leaving a small channel through its centre. The oesophagus was also pervious to the right of, and a little anterior to, the tumor. The mass was moderately vascular, whitish in color, and of the consistency of encephaloid. When flattened out it measured longitudinally four and a half inches, and transversely three inches. Dr. J. W. S. Arnold, who had examined the specimen, pronounced it to be one of cylindrical epithelioma. Dr. A. not being present, no detailed description was given of the appearances.

DR. DELAFIELD remarked that the specimen was interesting from the fact that the microscopical elements of the growth did not follow the type of the epithelium of the neighborhood. The specimen was then, on motion, referred to the Microscopical Committee.

ADENOMA OF THE BREAST.

DR. MASON presented a second specimen, which consisted of a tumor of the breast, which he had removed by operation from a female patient, thirty-two years of age, a dressmaker by occupation. Eight years previous to her admission she noticed a distinct tumor in the breast, which gradually grew until the whole organ became involved. Its increase in size was most marked and rapid during the past two years. The tumor was readily movable in every direction, and the skin was not adherent. There was no retraction of the nipple, neither was there any enlargement of the lymphatic glands in the neighborhood.

She never had any pain in the breast until a few months ago, when she experienced slight twinges through the tumor. The surface of the growth had a nodular feeling, and from the history of the case a diagnosis of adenoma was made. This diagnosis was confirmed by Dr. Delafield, who made a microscopic examination of the growth. Before its removal the breast measured eight and a half inches vertically, and nine and a quarter inches horizontally.

FALSE ELBOW JOINT.

DR. SAYRE presented a curious specimen of false elbow-joint, removed post-mortem from the body of a noted performer, whose varied motions of the arm in sword exercise had often astonished his spectators.

Dr. Wyeth, who removed the specimen, gave the following description of its peculiarities:—The biceps muscle was normal, as were also the relations of the brachial artery. The brachialis anticus muscle was attached firmly to the new capsular ligament formed around the false joint. The supinator longus was attached above and below the point of fracture on the external condyloid ridge, and was adherent to the new capsular ligament. The triceps extensor was attached not only to the olecranon process, but to the new capsular ligament and broken condyles of the humerus. The ulnar nerve was between the internal fractured condyle and the olecranon, and was liable to be pressed upon in certain motions of the artificial joint. The humerus was fractured obliquely from about two inches above the external condyle to about one and a half inches above the internal condyle. The elbow-joint was not interfered with by the accident. Between the fractured humerus a strong capsular ligament was formed, to which the integument was adherent behind. Between the false joint and the elbow-joint the condyles were split from each other, and there was free motion between the two condyles. The freedom of motion in the false joint was almost equal to a ball-and-socket articulation. There was two and a half inches shortening on the injured side.

DR. SAYRE remarked that the joint would be opened at a future time for the purpose of making a careful dissection, when the results would be presented to the Society.

MORBUS COXARIUS.

DR. SAYRE presented a specimen of morbus coxarius, consisting of portions of the head, neck, and acetabulum, removed by operation from a child aged six years. The interest of the specimen consisted in the existence of two bony points or spikes, which were inserted in corresponding perforations in the acetabulum. Dr. S. suspected this condition of things from the fact that there was more than ordinary difficulty, during the operation, in luxating the limb. He accordingly separated the head of the bone by a chain-saw, and picked it out from the acetabulum. In connection with this specimen he presented a similar one, remarking that in that particular instance he had fractured the thigh in attempts at luxation. The same accident occurred in another case of his, but was occasioned by his assistant, who, by the way, was father of the child. Since the occurrence of these accidents, Dr. S. was always careful to separate the head of the bone whenever there was any amount of resistance to attempts at luxation.

ANEURISM.

DR. LEALE presented an aneurism of the descending portion of the arch of the aorta, taken from a man aged forty-one, who previous to his marriage in May last had no unfavorable symptom. Soon after he

complained of pains about the head, but even these were not of much account. When Dr. Leale saw him he noticed a distention of the temporal arteries, and supposed there was a general atheromatous condition of the vessels. The patient soon after went under the care of another practitioner, and the next he saw of the case was at the autopsy. Death occurred suddenly, as the result of hemorrhage, and followed some gymnastic exercises. For some considerable period before his death he was anæmic. There was a circumscribed bronchitis, which was referable to pressure of the tumor upon the bronchus just above the bifurcation. During his lifetime he had been examined by a number of physicians, but no diagnosis of aneurism was made. At the autopsy an aneurismal tumor was discovered, not larger than an English walnut. It had ruptured through the œsophagus and had caused almost instant death by hemorrhage. The pressure of the sac upon the thoracic duct explained the anæmia which was so noticeable before death. The opening into the œsophagus was about the size of a twenty-five cent piece. The stomach was filled with blood. The tumor was almost completely filled with layers of fibrine, and the exertion which caused the rupture of the sac must have been considerable. In answer to a question, Dr. Leale stated that there had been a slight huskiness of the voice and some difficulty in swallowing.

PERICARDITIS—SIMULATED PNEUMONIA, ETC.

DR. DELAFIELD presented a specimen taken from a young woman, aged 27, who was admitted into Roosevelt Hospital, Jan. 29. Five days before her admission she had an attack of acute articular rheumatism. On the 29th day of January, it was noticed for the first time that there was a single systolic friction murmur, and on the next day a double friction murmur. On the first of Feb., the attending physicians changing service, the one who then came on duty added to the diagnosis of pericarditis that of double pneumonia. This latter diagnosis was based upon the existence of bronchial breathing and dullness over both lungs behind. The friction sound continued during the whole of the patient's illness. She became very sick towards the last, was very much cyanosed and delirious, and died in that condition.

At the autopsy it was found that the heart, as it lay in the thoracic cavity, occupied a much larger space than it should. The pericardium extended up to the top of the first rib, while the lateral measurements of the heart were larger than they should have been. On opening the pericardium, it was found that this increase in size was not altogether due to the accumulation of serum, but in a considerable measure to a thickening of the sac from deposits of fibrine; also to an increase in the size of the heart itself. The heart was enlarged, and there were vegetations both upon the aortic and mitral valves. Both pleural cavities contained a small amount of clear serum. The lungs were in a condition not unlike consolidation, were very much congested and œdematous, appearing as if compressed by pleuritic effusion.

The right and left lobes of the liver were considerably enlarged and congested, so that the level of the organ was to the top of the fourth rib. The other organs were congested, but otherwise there was nothing of special importance.

The principal point of interest in this case lay in the supposed existence of pneumonia. The bronchial breathing and dullness were, however, due to the compressed condition of the lung, which, in its turn, was due to the increased size of the heart, enlargement of the liver, and the accumulation of serum in the pleural

cavities. The specimen of pericarditis, as exhibited, was exceedingly well marked.

HOB-NAILED LIVER CAUSED BY CONTRACTION OF HEPATIC CELLS.

A second specimen, presented by Dr. Delafield, was removed from a man 56 years old, a liquor dealer, who was admitted to Roosevelt Hospital on the 23d of Dec., 1874. The man had always been a hard drinker, for the last three years of his life an habitual drunkard, and he had been in every way a very disreputable person. He had suffered from frequent attacks of headache, loss of appetite, and dyspeptic symptoms; but had been in fair health until four and a half months before his death. At that time, according to his account, he had an attack of typhoid fever. Within four weeks after his convalescence his abdomen and legs began to swell. He also became much emaciated, and had frequent attacks of epistaxis, but no hæmatemesis.

When admitted there was marked jaundice, as well as ascites and œdema of feet and scrotum. He was tapped for the ascites on Jan. 6, but with only temporary relief. The fluid reaccumulating, tapping was performed again on Feb. 3, and he died Feb. 7.

The principal point in this case was the liver. The history was evidently an ordinary one of cirrhosis. The organ was small in size, and only weighed about two pounds. Instead of having the ordinary nodular appearance of a cirrhotic liver, the *surface was perfectly smooth*, and even the capsule was not very much thickened. It was very evident, however, on looking at the organ with the naked eye, that there was a very marked increase of fibrous tissue, which had the ordinary character and appearance of new growth. This fact was of some importance in connection with the generally received idea that the ordinary "hobnailed" liver was caused by the contraction of this new tissue. In that specimen there was no contraction whatever. There was another point of interest in this liver, and that was the condition of the hepatic cells. These were hardly diseased at all, the majority having their normal appearance. The fact that the cells were not altered, according to Dr. Delafield's idea, explained the reason why the surface of the liver was smooth. He believed that the production of nodular liver was due more to the shrinkage in the cell element than to the contraction of the new-formed connective tissue. The kidneys were in a condition of chronic Bright's disease.

In connection with the rarity of this condition he remarked that the cirrhotic livers might be divided into large and small. In the first variety the organ might be nodular or smooth, in the second variety the same conditions might be seen, but it was exceedingly rare to find a small and smooth cirrhotic liver. He mentioned in passing that still another variety of cirrhotic liver was met with, but was still more rare. This was of syphilitic origin. The organ was about the medium size, but the fibrous tissue, instead of surrounding the acini, was found to separate the individual cells. He had met but two cases of the kind, one of which had also been examined by Dr. Satterthwaite.

The Society then went into executive session.

The President appointed the following gentlemen as members of the Microscopical Committee: Drs. E. G. Janeway, T. E. Satterthwaite, and J. W. S. Arnold. Adjourned.

THE ALUMNI OF THE MEDICAL COLLEGE OF OHIO met at Cincinnati on the 25th ult. and organized an association.

Correspondence.

WOUND OF HEART BY BUCKSHOT, AND RECOVERY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Thinking the following may be of general interest to the profession, I send it to you:

On the 15th inst. I received by express from Dr. Henry W. Haldeman, of Iowa, a box enclosing a heart, accompanied by a letter, from which I make the following extract:

"It is the heart of a deer, shot a few days ago by a hunter. You will discover an old cicatrix at the termination of which is lodged a buckshot, which inflicted the wound, I should think about a year previous. The pericardium was removed before I received it."

Unfortunately the buckshot had become dislodged, and was lost through the somewhat broken box.

The heart is apparently normal, except the cicatrix, and weighs one pound, all the vessels cut close to the heart. Placing it on what, in a human heart, would be its posterior surface, I find the left-ventricle, from base to apex, four inches and a half, and from the border of the ventricle to the line of the coronary artery marking the ventricle septum, is a nearly uniform width of about two inches. The cicatrix is on the anterior aspect in the wall of the left ventricle, extending in the line of the septum, but half an inch from it, for three inches, following the curve of the heart, and is half an inch wide, somewhat depressed, the most so near the apex. At the upper end of the cicatrix a part of the wall is cut out to show the cavity so long occupied by the buckshot, which was unfortunately lost. Along the line of the cicatrix the ventricular wall is three-fourths of an inch thick. Assuming that the shot struck the heart when dilated as it is now, it traversed the muscular structure nearly parallel to the septum for three inches.

Whether founded a year ago or less, the whole indication is complete recovery from the violence done at the time, and on that account is of value as showing that a severe wound of the heart is not necessarily fatal.

There is no indication of adhesion of the pericardium, which was removed by the hunter, and so far as appears received no attention.

Truly yours,

C. L. FORD.

UNIVERSITY OF MICHIGAN,
ANN ARBOR, MICH., Jan. 25, 1875.

ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS.—At a meeting, held Wednesday evening, Feb. 24th, the following officers were elected for the coming year: *President*, Alfred S. Purdy; *Vice-President*, William H. Draper; *Secretary*, George Bayles; *Assistant Secretary*, John N. Beekman; *Treasurer*, Timothy M. Cheesman; *Trustees*, Robert A. Barry, D. Tilden Brown, Gurdon Buck, Henry C. Eno, Thomas E. Satterthwaite. Dr. Robert F. Weir and Dr. A. Brayton Ball resigned from the Committee on Prize Essays, and gave as a reason that the author of one of the papers to be considered by the Prize Committee had become known to them. It was agreed that the time for the examination of the essays should be extended to elect other gentlemen in their places. □

Obituary.

JOHN McCLELLAND, M.D.,

NEW YORK.

JOHN McCLELLAND was born at Galway, Saratoga County, N. Y., April 23d, 1805. His grandfather, the Hon. Judge John McClelland, a native of Scotland, became an active participant in the War of Independence. Our lamented friend is said to have resembled him both in his physical and moral excellencies.

His father was a farmer of limited means, and required the services of his son until he became of age, when, contrary to parental wishes and advice, he resolved to study a profession, and at the age of twenty-two took up the Latin Grammar with the motto, "perseverentia et patientia vincunt omnia." He abandoned the plough, and, aided almost alone by that indomitable will and energy which he maintained through life, and which difficulties and obstacles only spur to increased vigor, he was enabled to take the degree of A. B. at Union College in the class of 1832—a class noted for many distinguished members, among whom we may mention as intimate friends of the deceased the Hon. Judge G. M. Speer, LL.D., and Hon. Judge Hamilton Robinson.

Dr. McClelland graduated at the College of Physicians and Surgeons in 1838, was appointed physician in charge of the New York Lunatic Asylum from June 10th, 1839, to September 22d, 1843, when his place was made vacant, and he commenced the practice of medicine in Bayard Street. The year following he was appointed Resident Physician of Bellevue Hospital, which position he held for one year, and discharged the duties of that responsible office with credit and honor.

In 1846 he resumed private practice at No. 261 Fourth Ave., and subsequently at No. 346 same avenue, where he applied himself assiduously to his profession day and night for nearly thirty years; ever mindful of his motto, he indulged in no recreation or social pleasures.

In 1872 his health began to fail, and he removed to 13 E. 66th Street, but continued to perform his professional duties, to the extent of his ability, until the 14th of February, when he was attacked with gastroenteritis, together with typhoid erysipelas, which terminated in his death at 7.45 A. M., February 20th, 1875.

From the beginning of his professional career he never refused his services and advice from any inability of the patient to make compensation.

His generous heart was seldom appealed to in vain by those whom he deemed worthy, and many a young physician will remember with gratitude his timely aid. His cordial and assuring manner at once won the confidence and love of those who sought his advice, which the tears of thousands to whom he had long become endeared, and who now mourn their loss, will abundantly attest.

E. H.

CHARLES B. COVENTRY,

OF UTICA, N. Y.

Dr. Charles B. Coventry, of Utica, Oneida County, died February ult., at his home. He was a son of Dr. Alexander Coventry, and was born in Deerfield, N. Y., on the 20th of April, 1801. After the usual course of study he was graduated as Doctor of Medicine in the spring of 1825, at the College of

Physicians and Surgeons of Western New York, at that time situated at Fairfield, Herkimer County, and during the same year entered into partnership with his father. In 1828 Dr. Coventry was appointed Lecturer on Materia Medica in the Berkshire Medical College at Pittsfield. After holding the position for three years he resigned it and began practice at Utica. The expected advent of the dreaded epidemic of 1832 caused him to be sent by the Common Council of the city to investigate the character of the disease, as it had already manifested itself in some of the Eastern cities. On his return he made a full report, which was published. His interest in the subject and the experience he afterward acquired when the cholera raged so fearfully gave origin to a later and valuable treatise from his pen. In 1839 he took part in the organization of a medical institution at Geneva, and again assumed the professorship of materia medica and obstetrics. The next year the chair was exchanged for that of obstetrics and medical jurisprudence. In 1846, in addition to the above post, he became Professor of Physiology and Medical Jurisprudence in the Buffalo Medical College, then just chartered. With this latter college he remained connected to the last, though of late only as Emeritus professor.

He was elected a member of the Medical Society of the State in 1841. In 1854 he became the President of the Society and read an address at the meeting in the following year, on "The Philosophy of Medicine as a Science and an Art." He contributed several valuable papers to the medical journals and to the transactions of the State Society.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from February 21st to February 27th, 1875.

SMITH, A. K., Surgeon.—Relieved from duty in District of New Mexico and assigned to duty at Fort Hayes, Kansas. S. O. 21, Department of the Missouri, February 18, 1875.

WHITE, R. H., Assistant Surgeon.—Granted leave of absence for two months, with permission to apply for an extension for six months. S. O. 41, Military Division of the Atlantic, February 26, 1875.

YEOMANS, A. A., Assistant Surgeon.—At the expiration of his present leave of absence to report in person to the commanding officer, Newport Barracks, Ky., for duty. S. O. 31, A. G. O., February 23, 1875.

ADAIR, G. W., Assistant Surgeon.—When relieved by Assistant Surgeon Yeomans, to report in person to the Commanding General Department of Texas, for assignment to duty. S. O. 31, C. S., A. G. O.

SUCCESSFUL TRANSFUSION.—*L'Imparziale*, No. 11, 1874, says that Professor Caselli performed this operation upon a girl affected with lipomania and stupor, who was unable to speak or to perform any movements at all complex. The blood used was taken from a sheep and flowed from the vessel at the rate of two ounces in fifteen seconds. It was conducted directly into the veins of the patient by means of a tube. After being allowed to flow for the quarter of a minute the transfusion was stopped and the patient appeared greatly revived, showed some color, took a deep inspiration, spoke a few words and made movements. The effect was persistent and recovery followed.

Medical Items and News.

DR. EDWARD DELAFIELD.—At an adjourned meeting of the Board of Trustees of the College of Physicians and Surgeons, held on the 18th ult., the following preamble and resolutions were unanimously adopted:

Whereas, since the last meeting of this Board, Edward Delafield, M.D., President of this College, departed this life on Feb. 13th, 1875, at the advanced age of eighty-one years, therefore be it

Resolved, That this Board enter upon its records, its high appreciation of the long-continued and valuable services rendered by him to this college. One of its earliest graduates, he served the institution as professor from 1826 to 1839, subsequently as trustee and vice-president, and since 1858 as president, until the time of his decease. This Board would express their deep sorrow at his departure.

Resolved, That during his long professional career, in which he attained a high rank as a learned instructor, no less than as a skilful and successful physician, his honorable conduct and great moral worth, his humane and sympathetic deportment, ennobled the profession of which he was a honored member.

Resolved, That the high reputation to which this college has attained, as one of the greatest medical schools of our country, is, in no small degree, to be attributed to his wise administration.

Resolved, That a copy of these resolutions, duly certified, be communicated to the family of the deceased.

Resolved, That these proceedings be published in the N. Y. MEDICAL RECORD and N. Y. Journal of Medicine.

Signed, J. G. ADAMS, M.D.,

GURDON BUCK, M.D.,

CAMBRIDGE LIVINGSTON, M.D.,

Committee of Trustees.

Feb. 18th, 1875.

NEW MEMBERS OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—LEON DE BRÉMON, 145 E. 21st Street, a graduate in medicine at the Academy of Paris, France, in 1867. THADDEUS M. B. CROSS, 37 W. 21st Street, a graduate in medicine at the Bellevue Hospital Medical College, in 1868. P. ALBERT MORROW, a graduate in medicine at the Medical Department of the University of the City of New York, in 1874.

BELLEVUE HOSPITAL MEDICAL COLLEGE COMMENCEMENT.—The fourteenth annual commencement of this school took place at the Academy of Music on the afternoon of Thursday, February 25th, ult.; one hundred and ninety-four students receiving the degree of doctor in medicine. The music by a grand orchestra under the direction of Mr. Bergmann, the leader of the Philharmonic Society, was very good. The Hon. John R. Brady delivered an address to the graduates, and John H. Duncan of the graduating class pronounced the valedictory.

The following prizes were awarded: Prize for the best standing in the general examination—Dr. Frederick S. Dennis, of the class of 1874, who obtained the prize of \$100 of that year, offered by Dr. James R. Taylor, offered the same prize to be competed for by members of the class of 1875. In making the award, the Faculty found it impossible to decide between two candidates who were of equal merit. The prize was therefore divided between LEONARD J. GORDON, of New Jersey, and LEOPOLD PUTZEL, of New York.

Two other prizes, offered by James R. Taylor,

of the class of '74, for general examinations ranking second and third in excellence, were awarded as follows: The second prize, of \$50, to HENRY M. SILVER, of New York; the third, of \$25, to CHARLES H. THOMAS, of Kentucky.

The prize of \$100 offered by Professor James R. Wood to the Alumni Association, for the best essay upon any subject connected with surgical pathology or operative surgery, was awarded to Dr. L. A. Stimpson, of the class of '74. Dr. Stimpson being in Europe, the Secretary received the prize for him.

The two prizes also offered by Professor Wood—one of \$50, the other of \$25, for the best preparations relating to surgical anatomy, were won by Dr. E. Morrison, of the Bellevue School, and Mr. Benjamin Benoit, Jr.

Professor A. B. Mott's prizes for the best reports of his clinique, were of \$50 and \$25 each, but were equally divided between A. J. Reynolds and N. A. Powell, whose reports were considered by Dr. Mott to be of equal worth.

The prize of \$50, offered by James Brice, Esq., to the graduate who should present the best inaugural thesis upon obstetric medicine, or diseases of women and children, was awarded to LEOPOLD PUTZEL. On account of the excellence of the thesis presented by L. J. GORDON, Professor Fordyce Barker added a second prize of \$25 in gold, which was awarded him.

Professor Flint, Jr., announced the establishment of the prize of \$100 by the Alumni Association, notice of which was given on page 136 of THE MEDICAL RECORD of Feb. 20th.

In the evening the Faculty entertained the graduating class, and a number of invited guests, at Delmonico's, where an elegant supper, music, and speeches brought to a happy close the most prosperous year the school has yet seen.

SCHOOL HYGIENE IN RHODE ISLAND.—We have been authoritatively informed that the R. I. Medical Society has not yet passed upon the resolutions concerning School Hygiene referred to on page 135.

THE COLLEGE OF PHYSICIANS AND SURGEONS.—The sixty-eighth annual Commencement exercises of the College of Physicians and Surgeons (Medical Department of Columbia College) were held on Tuesday evening, March 2d, at Steinway Hall. The Graduating Class numbered 108. Prof. Edward L. Beadle, Vice-President of the College, presided, and the platform was occupied by the Trustees and Professors of Columbia College, and a large number of members of the Faculty. The prayer of Bishop Hobart, specially composed for the college by that prelate, having been offered by Rev. Dr. Sullivan H. Weston, the degrees of M.D. were conferred. After the conferring of degrees, Dr. Beadle referred in eulogistic terms to the late Dr. Edward Delafield, and briefly sketched his career.

The following prizes were then announced by Prof. Dalton:

Faculty Prizes—First prize, William H. Welsh, A.B., Norfolk, Conn.; second, Joseph D. Anway, New York City. Honorable Mention—Edward Lasell Partridge, Lawrence, Mass.; John E. Stillwell, New York City; Howard Williams Longyear, Detroit, Mich.; James H. Casey, East Haven, Conn., and D. Bryson Delavan, New York City.

Prof. Thomas' prize case of surgical instruments, Alouzo Blauvelt, New York City.

Prof. Otis' prize, \$50, John E. Stillwell, New York City.

Prof. Seguin's prize, Alfred Masters, New York City.

In conclusion, Prof. Dalton announced that Dr. Oakley Vanderpoel offered a prize of \$50 for the best examination in anatomy, to be awarded at the Commencement exercises of the College in March, 1876.

The valedictory address was then delivered by Stephen S. Burt, a member of the graduating class, and the concluding address was delivered by Rev. Dr. Washburn. The exercises closed with the benediction.

THE WOMEN'S MEDICAL COLLEGE of Philadelphia has been made the recipient of \$50,000 from Mr. J. V. Williamson, to endow "free scholarships" in the school and "free beds" in the hospital attached to it.

A CENTENARIAN.—Canadian papers mention the death in Fingal, Ont., of Joseph Hyndman, a Scotchman, aged one hundred and five years.

THE GRADUATES OF THE UNIVERSITY, Medical Department, at its recent commencement, numbered ninety-five instead of eighty-six, as was stated in the city papers.

PHYSIOLOGICAL EXPERIMENTS UPON THE HUMAN CORPSE.—The experiments made by Drs. Keen and Seiler upon the body of Heidenblut, at Philadelphia, immediately after its removal from the gallows, showed that the internal intercostals are muscles of inspiration and the external intercostals muscles of expiration, the former lifting the ribs, the latter depressing them. In testing the facial muscles it was also shown that the pyramidalis nasi is a direct antagonist to the occipitofrontalis.

THE ART AND SCIENCE OF HANGING.—It is stated by the *Irish Times* that Professor Haughton, of Dublin, is writing a work on this subject.

INFLAMMABLE GAS FOUND IN THE STOMACH.—In the *Irish Hosp. Gaz.* is mentioned the case of a man who suffered eructations of gas after eating, and on four occasions the gas had caught fire, burning his lips and nose. He had symptoms of acid dyspepsia with dilatation of the stomach, probably owing to stricture of the pylorus. Analysis showed that the gas contained carbonic acid and hydrogen, the latter being the cause of its inflammability.

PHYSICIANS IN THE ITALIAN PARLIAMENT.—The profession is represented in the Italian Parliament by twelve physicians and surgeons, and an accoucheur.

DR. JOHN CROXON has been elected Professor of Midwifery in the Irish College of Surgeons, from among seven candidates. He is a well known and popular obstetrician; was formerly assistant physician in the Rotundo Hospital under the present master—whom he will probably succeed—and has for many years acted as examiner in the college.

THE NEW EDINBURGH UNIVERSITY BUILDING.—The plans for the new building for the Edinburgh school have just been adopted, and contemplate a hall in the form of a Greek theatre, capable of holding from 2,000 to at most 2,500 people; an anatomy class-room, circular in form, with a diameter of fifty-five feet, and intended to hold 400 students. Connected with the dissecting-room are to be a bone-room, a microscope-room, and apartments for injecting, etc. Class-rooms for surgery and practice of medicine, having a capacity for 250 students, a museum 112 by 40 feet, lighted from the roof, chemical laboratories, separate rooms for teaching materia medica, obstetrics, and jurisprudence, and reading-rooms for the faculty and students are also contemplated in the plan. A tower 230 feet high will serve as a belfry, and to give passage to two

large ventilating shafts. The estimated cost, without the tower, is \$350,000.

VACCINATION IN INDIA.—Indian medical officers demonstrate that the practice of vaccination is making considerable progress in that country. It is found that the "religious" objections of the natives to the operation can invariably be overcome by the payment of one ana (1½d.) per child.

SMALL-POX IN ROME.—Dr. Toscani has made an exceedingly interesting report of the recent epidemics of small-pox in the Italian capital, by which it appears that in the space of one hundred and thirty months, 3,149 persons were attacked, of whom 1,219 died, the first four being unvaccinated. In 2,770 cases the disease declared itself at the patients' homes; in three cases, at the hospitals; in fourteen cases, in the prisons; in twenty-seven, in the colleges and seminaries; while 245 patients belonged to the Agro Romano, and 90 to the contiguous districts. The poorer classes furnished nearly all the victims; the higher classes only twenty-two; the middle classes, including the Garrison, 233, the mechanics or working classes, 964. The persons vaccinated who were attacked, were 521, of whom 72 died, or 13.81 per cent. The persons not vaccinated who were attacked were 2,289, of whom 1,065 died, or 46.61 per cent. In 339 cases, of which 82 were fatal (24.30 per cent.), it could not be discovered whether vaccination had been practiced. The deaths varied in the following proportion, according to the place in which the patients were treated: at home, 46 deaths per 100 patients; at the Hospital of San Spirito, 23 per cent.; at San Giovanni in Laterano, 21 per cent.; at the Military Hospital, 8 per cent.; at the Hospital of the Fate-Ben-Fratelli, 36 per cent.; at the Lunatic Asylum, 60 per cent. Among those vaccinated the greatest number of deaths occurred between one, seven, fourteen, and thirty years of age.

THE ANNUAL REPORT OF THE ROTUNDA LYING-IN HOSPITAL, in Dublin, for 1874, shows that there were 1,236 deliveries in the year, and but 15 deaths from all causes, viz. placenta prævia, 1; apoplexy, 1; convulsions, 1; scarlatina, 3; bronchitis, 1; peritonitis, 5; pyæmia, 1; sloughing, 1; fatty degeneration of the liver, kidneys and heart, 1; typhus, 1; typhoid fever, 1. Only 997 of the deliveries were perfectly natural, terminating within twenty-four hours, and in 40 it lasted beyond that period. In 45 cases the ovum was expelled at the sixth month; and in 138 cases the forceps were used, 105 of the latter were in cases of primiparæ and of these five died. There were 24 cases of twins, and version was performed 14 times. *Post partum* hemorrhage occurred in 25 cases, and chloroform was administered to 104 women without any bad results.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, Mar. 8.—N. Y. Ophthalmological Society.

Tuesday, Mar. 9.—N. Y. Obstetrical Soc. Adjourned meeting at house of Dr. John G. Perry, 113 Madison Ave., "Lacerations of the Perineum;" paper by Dr. F. D. Lente. American Microscopical Soc. Yorkville Medical Assoc.

Saturday, Mar. 13.—N. Y. Med. and Surg. Soc.

Original Communications.

ON HYDROPHOBIA.

By JOHN G. JANEWAY, M.D.,

ASSISTANT-SURGEON U.S.A.

A WRITER* in the *American Journal of Science and Art*, May, 1874, states that "it is evidently my opinion that the malady produced by the mephitic virus is simply hydrophobia." Should he be correct, then all that is established by these facts would be this, viz.: "that henceforth the varieties mephitic must be classed with those animals that spontaneously generate poison in the glands of the mouth and communicate it by salivary inoculation." The personal observation of fifteen fatal cases of hydrophobia, produced by the bite of rabid animals, skunks, wolves, and hogs,† and the reliable statements of a number of other cases, has fully confirmed me in the opinion above stated, that the malady produced by mephitic virus is simply hydrophobia.

The following five cases are taken from the fifteen fatal cases that have fallen under my observation:

CASE I. BITE OF SKUNK.—Was called to visit Wm. P., aged nineteen, a herder, whom I was told by the messenger had been acting strangely all the morning. I found him lying on a bed in a sod-house, dressed, with several of his companions around him. Face flushed, pulse very rapid, the heat of skin intense and dry, eyes brilliant and pupils dilated rather more than natural, extremely restless and frequently catching at his throat; upon questioning, replied that his throat was turning into bone. Had not felt well for two or three days; did not know what was the matter with him. Upon pouring out some water from a pail near by, to administer morphia to him, he went suddenly into convulsions.

Suspecting hydrophobia immediately, as soon as he regained consciousness I learned that he had been bitten by a skunk, just before daybreak, seventeen days before, in the little finger of the left hand; that the wound was small and soon healed; that for two days preceding my seeing him his finger and arm had felt numb. Upon examining the finger, slight redness was observed at the place bitten, tongue slightly furred and somewhat swollen, no so-called "characteristic pustules" were to be seen. Thirst intense and begged for water, but the sound of dipping the water from the pail threw him immediately into still more terrible convulsions, frequent sighing, and catching his breath. Administer hypodermic injections of morphia without avail. Upon the arrival of chloroform, which I had sent for, its administration gave partial relief for a short time. His endeavors to free himself of the tenacious mucus were terrible, when the incautious upsetting of a pail of water again threw him into convulsions, opisthotonos in character, followed by attempts at biting those holding him, and, when consciousness was regained, asking pardon for so doing. Hyperesthesia existed in a very marked degree in this case. Death came to his relief in about eighteen hours from the time of his first convulsion.

CASE II. BITE OF SKUNK.—An emigrant from Wisconsin, camped on the north fork of Big Creek, about seven miles from Hays, applied to me in the fall of 1872 for dressing for his hand, which had been bitten between the thumb and index finger

of his left hand, the night previously, by a skunk. Cauterized the wound well, and directed him to repeat the cauterization twice a day. Saw nothing of him for twelve days, when I was sent for, and upon arriving at his camp found him in convulsions, which were repeated rapidly. Face flushed, eyes brilliant, pupils rather contracted, skin hot and dry, pulse small and rapid, 120, no so-called "characteristic pustules" under the tongue. When not in convulsions, mind clear and fully aware of the fate that awaited him. From his wife I learned that after the third day of using the caustic the wound healed and gave him no further trouble; that for three days he had been complaining of some fullness in the head, and a general "malaise," neither sick nor well; that the convulsions came on about seven hours previous to my seeing him, suddenly, upon attempting to take a drink from a spring close to their camp; that he would go into convulsions whenever water or tea was offered him, and that the faintest breath of air would cause him the greatest anguish, so that she had to put a blanket up before the door. Death followed in twenty-one hours after seizure.

CASE III. BITE OF SKUNK.—A hunter, in the latter part of October, 1872, applied to me to be treated for a bite through the right ala of the nose. He had been attacked by a skunk while in camp on the Smoky Hill river two nights previous. Having learned, previous to my seeing him, that skunk-bites would produce hydrophobia, he had imbibed freely, and was decidedly under the influence of liquor when I saw him, evidently nervous about himself, but trying to conceal the fact.

A stick of nitrate of silver was passed repeatedly through the wound. Actual cautery was proposed, but he would not consent to its use. After being under treatment two days he left and went to Missouri, to have the mad-stone applied; returning from there, he followed his occupation. Twenty-one days after he was bitten he was taken with convulsions, and died about an hour after I got to his ranch, nearly thirty hours after the seizure. From one of his companions I learned that after his return from Missouri he was cheerful and in apparent health up to the day before his seizure, when he complained of pain in his nose and face, headache, chilly, and feeling tired, but had no apprehension concerning himself. The first symptom, the morning the disease developed itself, was a feeling of constriction in the throat, together with dryness, opisthotonos, with decided mania preceding the spasms.

CASE IV. BITE OF WOLF.—A private of Co. F, Sixth Cavalry, was bitten by a wolf one evening, just after he had come off post, in the lobe of the left ear, in the early part of October, 1873. The wound was freely cauterized with nitrate of silver by the surgeon of the camp. On the 28th of the same month he applied to me for medicine for headache, which was given to him. On the 30th he again applied for medicine, stating that he did not feel sick enough to go on the sick report. Knowing the man's history, I cautiously examined him, and questioned him in such a way as not to excite his fears. I found that the lobe of the ear that had been bitten was quite numb to the touch. No other symptoms presented themselves prominently. There was, however, a general malaise. The day following, the man was in the ranks for muster and inspection. Observing him, I saw at once that something was wrong, and upon reporting his case he was ordered to his quarters, by the commanding officer. Fifteen minutes later I was sent for to see him, and found him in convulsions, which the orderly informed me came on upon his attempts to take a drink of water. He was at once removed to the hospital. He suffered from cold, he told

* Rev. Horace C. Hovey, M.A. † Skunks 10, wolves 3, hogs 2.

me, whilst being conveyed there. Examination revealed alternately contracting and dilating pupils; skin very hot; temperature 102°, 102.5°, 100°, by three examinations, with the thermometer in the axilla; pulse 120-125, alternating in volume before and after a spasm, but constantly rapid. Tongue somewhat swollen and indented by the teeth on the edge; thick, whitish fur; no so-called "characteristic pustules" under the tongue. Thirst intense; no irritability or sensation in the wound of the ear; constriction of the pharynx; increasing violent attempts to relieve himself of the thick and tenacious saliva; sound produced resembling more the bark of a wolf than any sound ever heard. Complete inability to swallow any liquid, the attempt ending in a convulsion. Mental faculties perfect when not in spasm; fully aware that death must end the scene. Towards the close the convulsions were longer and of greater strength, with frequent furious attempts to bite his attendants, for which he would beg their pardon time and again. Death took place suddenly in thirty hours.

CASE V. BITE OF DOG.—A man, aged about 46, attached to a hay-camp, applied to me in August, 1873, to dress his hand, which had been terribly lacerated by a favorite hound that day. He stated that his dog had been acting rather strangely for several days, but that up to that time had always come to him when called, and had appeared as affectionate as ever; that a strange dog had appeared in camp, and that his dog had attacked it furiously; he attempted to separate them, when his dog turned and bit him through the hand, his teeth passing completely through from side to side; that immediately after biting him he (dog) had run off a short distance and laid down in a pool of water. Can-terizing the wound freely I directed him to report at the hospital next morning, when the eschar was removed and his hand was again canterized. The following day he called at the hospital and stated that he had shot his dog, and was satisfied that he was mad, and that he was going that day to Missouri to have a mad-stone applied. He remained there a week, and then returned and rejoined the hay-camp. On the twenty-fourth day after he was bitten, I was sent for to visit him at the hay-camp, on the Smoky Hill river, lying in a wagon-bed, and was saluted with, "Doctor, that dog has killed me; I know that I have got the hydrophobia, and that I shall die." His face flushed; skin hot; pulse very rapid and small, 125; tongue furred, brownish, swollen; complained that his throat was turning into bone, and that he could not swallow; if he saw any liquid, thought he would like to drink a bucketful of water just once. On attempting to give him some morphia in solution the convulsions were ushered in. He had been well up to the morning he sent for me. The first symptom he noticed was the feeling of constriction in his throat, and he noticed a slight increase of redness in the wounds on his hand, though there was no pain. Had seen several cases of hydrophobia, and at the earnest solicitation of his wife had sent for me. Left him powders, of twenty grains each, hydrate chloral, to be given in moist sugar every three hours, and promised to see him next morning. I saw him the following morning, and found him decidedly worse; convulsions more frequent and stronger; pulse smaller and extremely rapid; tongue more swollen; no so-called "characteristic pustules" to be found after careful search; eyes brilliant, with rather a contracted pupil; great difficulty of swallowing, though he was able to sup up a little water through some straw from a covered cup; had considerable sleep from the chloral, but his stomach had rejected the last dose, and he was unable

to take any more; mental faculties clear, could tell the approach of a convulsion, and begged his wife and attendants to take care; much increase of the thick tenacious saliva, and greater difficulty in freeing himself of it. No alteration in appearance of wound. The convulsions became more frequent, stronger, and longer in duration. He insisted upon being chained down to the wagon bed to prevent his injuring any one. Chloroform was left, with directions as to use. The day following I found him barely alive, unconscious, with frequent feeble spasms. Death ended the terrible scene after thirty-seven hours of sufferings. In this case there was no marked hyperæsthesia of the skin complained of.

Neither can I agree with the writer of the paper mentioned above, that mephitic inoculation is sure death. For the result of one case of bite from a rabid skunk, which will be detailed more fully hereafter, the report of eight others (six hunters and two soldiers) that were bitten, and also from having in my possession two dogs, one a setter and the other a black-and-tan, which have been repeatedly bitten in encounters with these animals and have as yet never evinced any symptom of the disease, will not permit me to concur with him. That more cases, proportionally, may result fatally from the bite of this animal, than from the bite of rabid dogs or wolves, is probably, if not actually, the case; still, there are obvious reasons for it to be so. An animal nocturnal in its habits, generally timid, but armed with a powerful battery to resist any injury or affront; one that will not attempt to bite in defence until the secretion provided for it by nature is exhausted, loses that secretion by the disease. It is a well-authenticated fact that rabid skunks are entirely free from the odor so characteristic of these animals, which could not occur if the secretion was not exhausted, and forgetting its normal timidity will attack any person or animal he may come in contact with, biting the most exposed part of the body, the alæ of the nose, the lobe of the ear, the thumb, or one of the fingers, and passes on. Here is probably the reason these bites are more fatal than those of other animals—always in a vascular part not protected by clothing, which prevents by wiping away the poisonous saliva in the fierce attacks of the mad dog or wolf, and thus saves the life of the one bitten. At a frontier post* this was well illustrated. A mad wolf suddenly sprang upon the officer of the day, who was making his round, and bit him on the arm, through his clothing; passing on, he bit a sentinel on post in the wrist, between the sleeve of his coat and glove, and then sprang upon a woman who was nursing a child near by, and bit her on the shoulder through a thick woollen shawl. All the cases were treated the same. The officer and the woman escaped the dread disease, but the soldier died of hydrophobia. A recent writer† says in reference to bites of rabid dogs: "The documents of investigation furnish indications full of interest in regard to the more or less innocuousness of bites, according to the different parts of the body upon which they were inflicted. If we compare the fatal with the harmless bites made upon the same region, we find that out of thirty-two cases where the face was bitten, twenty-nine proved fatal, which gives these wounds a mortality of ninety per cent. Out of seventy-three cases, in which the wounds were upon the hands, they have been fatal in only forty-six cases, harmless in twenty-seven, giving an average mortality of sixty-three per cent. In comparing wounds of the arms and legs with those of the face

* Fort Larned, Kansas.

† H. Bouley, Gen. Inspector Vet. Schools of France, etc., etc.

and hands, the ratio is inverted; twenty-eight wounds upon the arms were followed by only eight fatal terminations, and twenty-four bites upon the lower limbs gave only seven fatal cases; seventeen remained harmless, showing a mortality of twenty-eight to twenty-nine per cent., and an innocuousness of seventy to twenty-one per cent., and, lastly, the ratio mortality for wounds upon the body is shown as follows: Out of nineteen bitten, twelve cases were fatal and seven bites proved harmless.

These facts are confirmatory of those afforded by other statistics, demonstrating also that rabid wounds upon uncovered or unprotected parts, such as the face and hands, are much more readily contagious than those of the arms and legs, which the teeth of the animal cannot reach without passing through a portion of the clothing, which wipes off the virulent moisture from the teeth. It is true the consequences of bites upon the body seem to conflict with this statement: but we must remember that generally these wounds are more severe, and among them some are uncovered parts, such as the neck and chest, and that, when a man is attacked by a rabid animal and bitten upon the body, he is also bitten upon his hands, which are his material means of defence. Another reason for the apparent large proportion of fatal cases from skunk bite is, that it is only since 1871 that these cases have been collected, or that the fact of hydrophobia existing in and following the bites of these animals has been generally known, and only those cases proving fatal have been reported, the non-fatal cases, from the trivial character of the wound, not being considered of sufficient importance to report.

A CASE OF SKUNK BITE *not* FATAL.

W., a young man, twenty-two years old, born in Missouri, commonly known by the soubriquet "Pike County," driving a team for a party of emigrants for Colorado, was bitten at night, in the early part of May, 1874, upon left cheek, by a skunk, whilst camped at Park's Fort,* Kansas. A companion, who was bitten by the same animal, freely cauterized the wound. Early the next day he presented himself at the hospital for treatment. Removing the eschar I cauterized it again freely with caustic, and directed that he take $\frac{1}{16}$ th grain of strychnia every three hours during the day, with vegetable tonics and full diet, the wound to be cauterized morning and night, and a poultice to be applied one hour before retouching to remove the eschar and promote suppuration. No characteristic symptoms being produced by the strychnia on the fourth day, it was increased to $\frac{1}{12}$ th grain dose, given as before. Suppuration was fairly set up in the wound and continued; four days after, strychnia increased to grain $\frac{1}{8}$ th, and continued at that for four days without any symptoms of its toxic effects. The dose was then increased to grain $\frac{1}{4}$ th, and continued for six days without the patient being conscious of any jerking, though the night nurse and some of the patients stated that he jerked somewhat more than natural when asleep. Suppuration of the wound continued free under the caustic and poultices; the dose of strychnia was then increased to grain $\frac{1}{2}$, and I watched him very carefully, for the slightest appearance of the effect of the medicine, for six days. On the last day I detected some slight involuntary twitching of the muscles of the face, and reduced the dose. Two days after reducing he remarked that he guessed that he was safe from hydrophobia, as the strychnia had not killed him. The wound was allowed to heal up, which

it did rapidly, and a few days after he left the hospital, and I saw him three months after perfectly well.

The above case shows either, first, that the man was not inoculated by the virus when bitten; second, a wonderful tolerance for the drug if he was not so inoculated; or, third, that acting primarily as a tonic to the nerve elements it enabled them to resist the invasion of the disease, and together with the frequent cauterization and free suppuration, to eliminate the poison from the system. (That the strychnia used was a good article was proved by the effect of a small dose upon an obnoxious cur of medium size.) I am inclined to the latter, for that the animal causing the wound was undoubtedly rabid is proved by the fact that the companion who was bitten by the same animal, in the camp, on the same evening, was reported to have died from hydrophobia about ten days after being bitten, and should another case present, would adopt the same treatment and push the drug until its characteristic effects upon the system presented.

Rabies Mephitica, like Rabies Canina, is evidently epidemical, no cases of it having been reported previous to 1870 in this region.

The period of incubation is alike in Rabies Canina and Rabies Mephitica (so called), that is, it is indefinite, ranging from ten days to ninety days, no opportunity in the meanwhile being afforded for subsequent inoculation of hydrophobia. Statistics show that the manifestations of the disease have been most numerous during the first sixty days, and that after a bite from a rabid animal the probabilities of escape increase considerably when sixty days have passed and no symptoms of the disease have shown themselves, and that after the ninety days entire immunity is almost certain. Still, I am aware that cases are reported of a longer period of incubation. These are exceptional, and when reported to extend beyond the fourth month it may be questioned whether the patient has not been unconsciously inoculated by the carcases of a pet dog, suffering from the disease unsuspected, from tetanus, or, as Baron Larrey* remarked, when commenting upon Dr. Fereol's case of hydrophobia with two years and a half incubation: "For my part I should be disposed to regard his case not as an example of rabies, with an incubation of two years and a half, but as one of cerebral hydrophobia or symptomatic of acute delirium, provoked or aggravated by the coincidence of the bite of a dog presumed to be mad." In all the cases from the bite of a skunk the prodromic stage of the disease was more or less marked, though none of them amounting to acute melancholy. An indefinite feeling of dread and a general malaise—the most prominent symptoms, together, in most cases, with pain or numbness at the seat of the wound, were present from one to three days. To most of these unfortunates the fearful results of the trivial wound they had received was unknown, and unaware of their perilous condition were not incessantly tormented with sad forebodings or dread of the onset of the malady.

2. The characteristic pustules which the writer of Rabies Mephitica lays stress upon were not found in any of the cases of hydrophobia produced either by the bite of the skunk, wolf, or dog. Niemeyer † states that "the assertions of Marochetti, who claims that during the incubation stage vesicles form beneath the tongue, and that by destroying these vesicles the outbreak of the disease can be averted, have not been substantiated."

* Park's Fort, K. P. R. W.

* London *Medical Times and Gazette*, Aug. 8, 1874, p. 159.

† Niemeyer, *Pract. of Med.*

3. That the invariable accompaniments of Rabies Canina were not wanting in the cases of R. Mephitica. The specific action of the poison was made manifest first by the œsophageal branch of the eighth pair, giving rise to the characteristic symptom of the disease, or to the extreme difficulty of swallowing, especially of fluids; then the frequent catching of breath noticed in all cases, showing that the recurrent nerve was also affected; later brilliant eye, and the sense of touch becomes painfully excited, hyperæsthesia existing in a marked degree, with the exception of the case reported of R. Canina, all of which point to some lesion of the central and spinal nerves. That the brain itself, and especially the region of the medulla oblongata becomes affected by the terrible convulsions and delirium in the more advanced stage of the malady. The spasms in all the cases were unlike those of tetanus, less continuous, remittent, and often intermittent. In none of the cases produced by the skunk bite was there any loss of perception. In no case that I saw did morphia have any effect in abridging the fearful struggles; death either ended with convulsions, or exhausted by the terrible exertions a sudden calm took place, and, as if nature gave up the conflict, died without a groan.

A CASE OF SYPHILITIC ATROPHY OF BOTH OPTIC NERVES.

By FRANK H. RANKIN, M.D.,

ASSISTANT SURGEON AT THE MANHATTAN EYE AND EAR HOSPITAL,
CLINICAL ASSISTANT AT THE UNIVERSITY MEDICAL
COLLEGE, NEW YORK.

THE case presented occurred in the service of Dr. Roosa, at the Manhattan Eye and Ear Hospital, and for the first two months of attendance, during Dr. R.'s absence for the summer, came directly under my care.

E. T., æt. 27, was admitted to the hospital as an out-door patient on the 21st July, 1874, and gave the following history: About five months ago he commenced to complain of intense cephalalgia—pain confined almost entirely to the left side of the head and occiput. Suffered continually with headache for over a month without seeking medical aid; the headache growing more and more severe every week, till finally he was forced to go to bed, and a physician called in, who pronounced the patient to be suffering from inflammation of the brain. Patient was confined to his bed for five weeks, during the greater part of the time suffering with intense hemicrania; had high fever, was troubled a great deal with nausea, but did not vomit; bowels very constipated, requiring medicine to move them; patient would wander in talking, but had no active delirium; had hallucinations, photophobia, and impairment of vision. When he was able to leave his bed his vision was apparently normal, as he states he was able to read the newspaper without difficulty.

Ten years ago he had a chancre and bubo. Four years ago he had a sore on his penis, which, he says, healed in about ten days. During the past four years he has suffered with troublesome sore throat, and also with an eruption on the skin. Never had any alopecia. Last fall was laid up with inflammatory rheumatism.

Since his sickness in March he has felt very much prostrated, but has been comparatively free from headache. Eye-sight apparently perfectly good till five weeks ago, three weeks after leaving his bed, when he noticed the sight gradually failing in the left eye. On presenting himself at the hospital he was very anæmic, had loss of appetite, and appeared generally broken down in health. He had a perfect

amaurotic stare, and was unable to find his way freely alone. Pupils moderately dilated, and their reaction to light good. With the left eye there was barely perception of light on the nasal side; on the temporal side there was no perception of light. With the right eye vision = $\frac{1}{200}$, no improvement with glasses. Field of vision in left eye, nil; field of vision in the right eye contracted on the inner and upper, and the inner and lower segments almost to the point of fixation. The ophthalmoscopic examination showed atrophy of both optic nerves, more marked in the left. Both disks of a bluish-white color, have an irregular shrunken border on their nasal side. The choroidal ring on the temporal side cannot be made out. A central physiological excavation in both optic disks; the small nutritive vessels on the expansion of the pupillæ have entirely disappeared, and the retinal arteries are much diminished in calibre. Some choroiditis in both eyes.

Treatment.—Ordered an iron and quinine tonic; daily hypodermic injections of nitrate of strychnine in increasing doses, commencing with a $\frac{1}{8}$ th gr.; cod-liver oil, hydrarg. protiodid. $\frac{1}{2}$ gr. daily, and to wear blue glasses.

July 27th.—At the suggestion of Dr. Sturgis, discontinued the protiodid, and substituted the ung. hydrarg., a drachm to be rubbed in every night.

July 30th.—Gums slightly tender. Ordered potass. iodid. gr. viij. three times daily, increasing three grains a day.

August 4th.—Patient is now receiving $\frac{1}{12}$ th gr. strychnia and taking 48 gr. potass. iodid. a day. Health very much improved. Vision in right eye = $\frac{200}{200}$, with the left eye can count fingers at three feet.

August 6th.—Vision in right eye = $\frac{200}{200}$ indistinctly; vision in left eye $\frac{200}{200}$ indistinctly. Reads No. 12 Jaeger at 10" with right eye, and No. 19 Jaeger at 12" with left eye; received to-day $\frac{1}{10}$ th gr. strychnia, hypodermically.

August 9th.—Received yesterday and to-day $\frac{1}{8}$ th of a gr. of strychnia. The patient was unable to walk for nearly an hour after receiving the injection to-day. The toxic effect of the strychnine being shown merely by stiffness of the legs; this was quickly removed after taking a good dose of bromide of potash. Patient is now taking 75 grains of iodide of potash a day.

August 18th.—Have not seen the patient during the past six days, during which time he has been taking $\frac{1}{10}$ th of a grain of strychnine by the mouth daily; is now taking 90 grains of potash a day. Vision in right eye = $\frac{200}{100}$, can make out $\frac{2}{7}$ imperfectly; vision in left eye $\frac{200}{100}$ indistinctly. Reads with right eye No. 8 Jaeger at 10", and with left eye No. 11 at 10". Resumed the daily injection of $\frac{1}{12}$ th gr. strychnine.

August 24th.—Vision in right eye $\frac{200}{100}$; vision in left eye $\frac{200}{100}$ indistinctly. Field of vision pretty good in both eyes; contracted on the upper and inner, and lower and inner segments.

Sept. 1st.—Vision in right eye, $\frac{200}{100}$; vision in left eye, $\frac{200}{100}$. Can read with right eye alone No. 2 Jaeger, and with the left eye alone No. 3 Jaeger at 7"; with both eyes together No. 1 Jaeger (diamond type) at 6". Discontinued the ung. hydrarg. and substituted the protiodid., $\frac{3}{4}$ th gr. daily. Strychnine injections are now given every other day. Patient is taking 125 grains of iodide of potash a day.

Sept. 19th.—Patient has not been seen for several days. He is now suffering quite severely from mercurial stomatitis. The protiodide discontinued. Re-commenced the daily injections of strychnine. Vision not so good as at last date.

Sept. 25th.—General condition not so good. Patient

says he has not taken the cod-liver oil or potash for the past week on account of soreness of the mouth. Ordered to recommence both. Stomatitis about well. Vision in right eye, $\frac{2}{30}$; vision in left eye, $\frac{2}{30}$.

Oct. 12th.—Vision in right eye, $\frac{2}{30}$, imperfectly; vision in left eye, $\frac{2}{30}$. The outlines of the disks on the temporal side are much more clearly marked; on the nasal side the papillæ have the same angular shape as seen at first. The optic disks still present the same brilliant pearly or bluish-white appearance, and there is an entire absence of the nutritive vessels on their surfaces. The principal retinal vessels have regained their normal calibre. In the left eye the twigs usually seen running outward from the retinal arteries as they come out of the disk are absent. General condition of the patient good; says he has not felt so well in ten years. Strychnine discontinued.

Oct. 16th.—Vision in both eyes, $\frac{2}{30}$, imperfectly. Reads No. 1 Jaeger at 7". All medicine discontinued excepting the iodide of potash, which he is to take for two months, 15 grains three times a day.

Jan. 24, 1875.—Patient appears in perfect health, says he can see as good as he ever could in his life. Vision $\frac{2}{30}$, imperfectly. Ophthalmoscopic examination showed the optic papillæ to be in the same condition as reported on October 12th.

Feb. 18th.—Patient returned to-day, vision in both eyes perfectly normal.

REMARKS.

The unusually favorable results obtained in this case may, I think, be attributed to the fact that the patient came under treatment very soon after the trouble in the eyes set in, and also to very rapidly pushing, to their fullest physiological effect, the mercury, strychnine, and iodide of potash. The mercury, however, was carried a little beyond the desired point, and quite a severe attack of stomatitis was the result. This quickly yielded after using chlorate of potash and alum as a wash, and, with the exception of a temporary retrogression in the condition of the eye, no harm was done.

This case is of especial interest in showing the compatibility of what appears on ophthalmoscopic examination to be marked atrophy of both optic nerves, with still remaining perfect vision; this may perhaps be accounted for on the supposition that the nerve fibres of the retina were unaffected, and that the atrophy was limited only to the head of the optic papillæ.

117 EAST 26TH STREET.

SOME FACTS CONCERNING PNEUMONIA.

By W. B. RODMAN, M.D.,

FRANKFORT, KY.

SINCE August, 1871, I have had charge of Kentucky State Prison Hospital. But a very short time elapsed before my attention was called to the immense number of pneumonia cases which I had to attend. Since the 1st of January, 1874, I have kept an accurate record of all the cases which occurred during the year, intending to report them. I did this because I believe my advantages for studying the disease have been equal, at least, to almost any man's in the country. This remark will seem reasonable when I say that during the year 1874 seventy-five well-marked cases of pneumonia occurred in my hospital. I have treated this year sixteen cases, and have now seven on bed.

I saw at once that these pneumonias were somewhat different from any that I had ever met with in private practice. Just here I will give a partial description

of the disease. The patient has a chill, which generally occurs in his cell at night. In the morning when he reports himself to the hospital he has cough, slight pain in the side (generally under the nipple), temperature from 103° to 105° , pulse from 120 to 150, respiration from 30 to 50. I find on percussion, slight dulness over the whole of the posterior aspect of one lung, and very frequently both. Auscultation reveals fearful congestion, as evidenced by weak respiratory murmur and the crepitant râles. One marked peculiarity is, that the whole posterior part of both lungs is frequently involved, while nothing but puerile respiration is heard in front. Most of the deaths have occurred in the first three days of the disease, from extent of the pneumonic process or collateral œdema of the lung. Frequently, in the first twenty-four hours, and on two occasions in less than twelve hours from their admission to the hospital, have patients died. In these rapid cases perspiration was very profuse, intellect slightly clouded, pulse rapid, soft, and small, respiration rapid, and death taking place in a temperature ranging from 101° to 103° . The sputa in all cases has been wonderfully profuse, sometimes reaching two pints a day, though this amount is exceptional. The color ranges from the ordinary brick dust to the prune juice, sometimes it is a dusky brown or black.

I have tried to understand the proper etiology of these cases, but cannot say that I have fully succeeded. The prison is built on "made ground," in other words, on a reclaimed marsh. The cell-house, in my opinion, is the principal cause of the prevalence of pneumonia. Seven hundred men sleep in cells that contain not more than 300 cubic feet of air each. The building itself is imperfectly ventilated. The house was originally designed to accommodate 250 men, additions being made by new stories as the number of prisoners increased. The whole number of stories is at present six. Four hundred and fifty men are engaged in hackling, spinning, and weaving hemp. Two hundred and fifty are in the blacksmith, carpenter, chair, and cooper shops principally. I for a long time supposed that the inhalation of the lint and dust from the hemp was the principal cause; but thirty-five colored female prisoners are engaged in spinning hemp, but having large, well-warmed, and ventilated cells to sleep in, they have no pneumonia. In fact, I had not a single case of pneumonia among the female prisoners last year. Throughout the hemp-raising district of Kentucky this article is handled exactly as it is in the prison; but on inquiry I find that the men (principally negroes) so employed are not more liable to the disease than those following other pursuits. It is true that, proportionally, more of the men employed in the hemp factory have pneumonia than those in the other shops; but, in view of the above facts, I cannot but believe that the cells in which they sleep greatly increase their liability to become affected.

Post-mortem examinations reveal just such changes in the lung as are found in ordinary pneumonia, except the amount of lung-tissue involved, and that occasionally the smaller bronchial tubes are choked up by dust and lint from the hemp. In these latter the sputum is pathognomonic of the disease—the color a dirty brownish black. The amount of lung involved has never been less than one-half of the breathing capacity. That is to say, either one lung entire, or more frequently the posterior halves of both lungs. In one case a heart clot was found extending from the chordæ tendinæ of the left ventricle *through the aorta to a point opposite the umbilicus*. As stated above, all the deaths last year occurred during the first three

days, only one dying later in the disease. In this case the whole of the left lung was in the third stage.

More negroes than whites die in proportion to the number attacked, although the cases are about evenly divided between the two races. The number of each race in prison is about the same.

The mortality last year of primary uncomplicated cases was 8 per cent., six deaths in seventy-five cases. When the character of these cases is considered, it must be confessed that this is a low rate of mortality. I would remark here, that since I have followed my present plan of treatment, I have not lost a single case of pneumonia or capillary bronchitis in private practice. I have in this time (since Jan., 1873) treated twenty-three cases, the age ranging from three months to eighty-one years.

The usual causes of death from pneumonia, according to Niemeyer, are hyperæmia and collateral œdema in the first stage, extensive inflammation in the second. A very high temperature also may produce an unfavorable termination; but by far the most usual cause of death is exhaustion after the second stage is completed. As my cases died (with the exception mentioned) during the first three days, death must have been produced by hyperæmia, œdema, or vast extension of hepatization. The physical signs, the immense quantity of frothy sputa, and the autopsies induce me to believe that collateral œdema was the principal cause.

When a patient with pneumonia presents himself at the hospital, he is thoroughly bathed with warm water, a mustard emetic is then given, and free vomiting is produced. The bowels, if constipated, are moved with some saline, generally magnes. sulph. and potass. bitart. The whole of the affected lung (or lungs, as the case may be) is enveloped in a turpentine stupe, and this remains until the second stage begins. Warm, moist applications are now applied, either woollen cloths wrung out of hot mustard water, or flax-seed poultices covering the whole lung. So soon as his bowels are opened, he is given the carb. ammonia, fifteen grains in mucilage acacie every three hours, with three grains quinine with each dose. From the beginning his diet is most liberal, consisting of beef-tea, milk, eggs, &c. As soon as the second stage sets in, whisky is added to the above, p. r. n. Sometimes as much as one and a half pints or a quart being administered in the twenty-four hours. The carb. ammonia is kept up until resolution has been fully established, as is the quinine. Opium is rarely given, especially in the latter stages. I rely more on the turpentine stupes to relieve pain. If there is not much accumulation in the bronchial tubes, ten grains of Dover powder are given at night. Blisters are not often used. But when the dulness, &c., remains longer than is usual, blisters have been used with marked success.

This, then, is the treatment for the ordinary cases. When the temperature is high, say 104° or 105° (occasionally $106\frac{1}{2}$ and the patients ultimately recover), quinine is given in large doses (10 and 15 grs.) for its antipyretic effect. If this is not sufficient, the wet pack is used to assist in abating the fever. I have tried Niemeyer's plan of cold-water treatment for the pneumonia proper, but have not been gratified with the effects. I use the cold water only for the purpose mentioned above. I have also tried to relieve the collateral œdema by bleeding, but have abandoned this method and substituted for it a mustard emetic. I have reason to believe, that by the timely administration of the emetic, more than one life has been saved. Towards the latter stages, if the pulse should become

weak and frequent (showing a weakened action of the heart from exhaustion) digitalis has been used with gratifying results. I have frequently found it beneficial, if there should be any decided typhoid symptoms, to administer a solution of potass. chlorate and mur. tr. ferri in connection with the above, say 5 grs. potass. chl. with 30 gtt. mur. tr. ferri every four hours. Recently very many of my cases, both in the prison and out, have had malarial complications. These are shown by a difference of at least 2° or 3° between minimum and maximum daily temperature and are almost certain to be present when the temperature is reversed, that is, when the fever is higher in morning than in the evening. Herpes, also, is most frequently present in abundance when there are malarial features. Large doses of quinine, as much as 3 i. per diem, have always removed this trouble.

I have tried other treatment than this with my pneumonia cases; for instance, sol. ammon. acet., ipecac, calomel, nitrate potass, etc., but finally abandoned all these and adopted the treatment above mentioned. I have reduced the mortality of pneumonia in the prison more than 50 per cent. by this plan. It may be said that a treatment which shows a mortality of 8 per cent. should not be relied on. In answer to this I say, that very few men can realize the fearful cases with which I have to contend. My men are convicts, have lain in dirty county jails, been poorly fed, exposed to all sorts of weather, broken down (many of them) in body and spirit, and in addition to all this, have attacks such as would produce a greater rate of mortality in persons more fortunately situated, under most of the plans of treatment now followed. This fact also I will mention again, that I have not lost a single case of pneumonia, in private practice, since adopting my present treatment. I can recall five cases of double pneumonia, in my own practice and in consultation, which I firmly believe would have died under any other plan than the one above.

I do not claim anything new or startling in this treatment; but I have found it difficult to impress some of my medical brethren with the value of carb. ammonia used from the *very beginning* of the attack. How this medicine acts, I do not know. If it succeed by preventing hyperæmia, why would not large doses of any other of the alkalies do as well? If by its stimulant properties, why will not other stimulants accomplish similar results? I do not believe that it does much good as an expectorant, as both my reading and experience teach me to rely but little on expectorants in pneumonia, a good mustard emetic being the best I know. I believe that carb. ammonia exercises some specific influence on the air vesicles themselves; this, however, is a *questio vexata* which wiser heads than mine must determine.

EXHIBITION OF LIFE-SAVING APPARATUS.—The Royal Life-Saving Society of Belgium has arranged to hold an international exhibition of life-saving appliances for safety, ventilation, and health at Brussels, in June, 1876. The machinery and apparatus to be exhibited will be classified as follows: 1, for saving life in case of fire; 2, in case of shipwreck or drowning; 3, in case of accident from locomotion on roads and railways; 4, in case of war; 5, for health and sanitary measures; 6, for health and ventilation in mines, factories, and workshops; 7, for household and private hygiene; 8, for institutions, associations, and societies organized for improving the condition of the working man; 9, for medicine, surgery, and pharmacy in their relation to the above classes.

Progress of Medical Science.

TREATMENT OF ACUTE RHEUMATISM BY THE PACKING PROCESS.—Dr. Dowse, of London, has recently been advocating the above method. He says the first thing to do in the treatment of rheumatic fever is to eliminate the acid products of the diseased state; and the next, to relieve pain. To bring this about he has been in the habit of packing most of his cases in a wet blanket, and then rolling them up in dry blankets, so as to produce profuse sweating, and also increase the temperature. Finding that this method gave good results, he adopted a systematic mode of procedure, which he thus describes: The bed is covered with India-rubber sheeting; over this is laid a blanket which has been wrung out of hot water. The patient is then enveloped in the blanket, and covered with six folds of dry blanketing. By this the temperature is raised, and profuse sweating results; the former, if need be, is assisted by the administration of brandy in half-ounce or ounce doses every hour, and the latter by freely drinking warm milk and water. If the temperature exceed 102 F., the stimulant is unnecessary. The treatment is continued for three days. He finds that after the third pack the pain completely subsides and the sour taste usually disappears. He gives the detailed histories of six cases, taken from some thirty which had been submitted to the packing process, and of which only one had failed of success. The author is of the opinion that the constitution or age of the patient does not so much influence the duration of the disease as the season of the year and state of the atmosphere, and he has repeatedly observed that if a patient with acute rheumatism in one ward had a relapse, it invariably followed that patients in other wards were similarly influenced. To carry out the treatment without failure, the prescribed regulations must be strictly adhered to.—*British Medical Journal*, January 23, 1875.

OPTIC NEURITIS WITH RECOVERY UNDER TREATMENT.—At a recent meeting of the Clinical Society of London, Dr. Thorowgood reported a very interesting case which he had observed with Mr. Vernon, and called attention to the value of ophthalmoscopic examinations in cerebral disease, and the efficacy of mercury in effecting a cure. The patient was a girl, aged 12, who gave the following history: Five weeks previously she received a blow upon the lower part of the back. Liniments were used and she was quickly relieved. But a short time afterwards, however, she felt pain in the back part of her neck, and it was accompanied with tenderness, swelling, and stiffness. A week later she noticed a fog before her eyes, and it gradually increased until vision was completely lost in both eyes, the patient being only able to distinguish between light and shade. On examination with the ophthalmoscope the optic discs were found swollen, with irregular outlines; the veins were engorged and obscured in places; the fundus oculi was paler and more yellow than usual. There were no hemorrhages. The same description applied to both eyes. The urine was free from albumen; the thoracic organs were healthy.

Leeches were applied to the temples, and three grains of mercury with chalk were given every three hours. Subsequently the liquor hydrargyri perchloridi was given in thirty minimi doses three times daily. Under this treatment, in combination with iodide of potas-

sium and the liquor strychnie with iron, the patient improved, and two months after the commencement of the treatment was able to read well. After the lapse of two more months she was again seen and her vision was declared normal. The left eye was rather better than the right, which was perhaps not quite up to the normal range. The optic discs looked pale and anæmic. In commenting on the case both authors regarded it as one of true optic neuritis, and not of *stauungs-pupille* or "choked disc." The principal lesion was thought to be basic meningitis, extending to and involving the optic nerves. It was believed also that this case was proof of the value of the ophthalmoscope in detecting meningitis, and showed the appropriateness of local depletion and mercurials in affections of this sort.—*British Med. Journal*, Jan. 30, 1875.

EPHEMERAL PARALYSIS.—The loss of function in the arm or leg of a child may often simulate a paralysis symptomatic of a lesion of the nerve centres. The physician adopts the idea of a paralysis, while there is often only a muscular atony which disappears in a short time, as in the following cases, narrated by Simon in the *Gaz. des Hôpitaux*, No. 125.

A child, eight months old, was thought to have had a paralysis of the left arm for two days. The sensibility was maintained; the muscles appeared to be more than usually painful; there was no luxation or fracture of any of the bones; the other functions were normal. The history pointed to a compression or jolt communicated to the shoulder-joint by the nurse. Warm fomentations with a liniment of belladonna, jessamine, and laudanum were ordered. The arm was enveloped in wadding, covered with India-rubber tissue, and the child recovered in two weeks.

A child, five years of age, after sitting on the grass for some time with its right leg flexed under the nates, was unable to move the limb on rising. Sensibility was diminished, and motion was impossible, while it was quite certain that there was neither fever nor any injury such as fracture or dislocation. By the same treatment as in the other case all the symptoms of paralysis ceased in three days.

The author calls the attention of physicians to the diagnosis, treatment, and prognosis of such temporal or rather false paralyzes.—*Giorn. Veneto di Sci. Med.*, Dec. 1874.

THE PATHOLOGY OF THE GREAT SYMPATHETIC.—Dr. A. De Giovanni has made a preliminary report (*Atti del R. Ist. Lomb. di Scienze Med.*, May 21, 1874) on some original investigations made to determine the extent to which these nerves alone may constitute an anatomical basis of special forms of disease. Several interesting cases are presented, among them one of a man forty-three years of age, who had gastric derangement, occasionally experienced a pricking sensation in the right border of the tongue near the apex, then a painful smarting, and at last a sensation of enlargement of the organ. The tongue began to swell, and then becoming too large for the oral cavity, protruded so as to embarrass respiration. This phenomenon occurred at intervals of from twenty to thirty days, ceasing sometimes on the application of ice, and occasionally after scarification, but it always occurred in connection with abnormal gastric functions. One day after the application of the ice the tumefaction of the tongue disappeared, as if by enchantment; but in a few hours an erysipelatous redness and swelling appeared on the scrotum and in the inguinal region, which, however, disappeared after local applications. Two other similar cases of gastric catarrh, with dys-

pepsia and recurrent enlargement of the tongue, are cited. The lingual symptoms are attributed to a disturbance of the equilibrium of the circulation, produced by anomalous action of the vasor nerves, excited by reflex influence from the stomach. In the three cases an habitual dyspepsia pre-existed, and the tongue became hyperæmic after the principal meal; hyperæmia of the spleen was not followed by other affections of the mouth, and the occurrence ceased after the cure of the gastric affection.

The author, in allusion to the source of the lymphatic elements that infiltrate the ganglia in certain morbid conditions, believes that these elements are derived solely from the vessels, and especially from the proliferation of the nuclei of the vascular walls.—*Giorn. Veneto di Sci. Med.*, Dec., 1874.

ENDOCARDITIS FROM MALARIAL INFECTION.—It is said that an alteration of the blood, produced by paludal infection, may, as in variola, be the cause of endocardial lesions. Among the various species of ulcerous endocarditis it would appear that we must now reckon another as the effect of this form of poisoning. That which follows rheumatism becomes generalized in the entire circumference of the mitral orifice, and gives rise to the formation of a tissue which has a tendency to become organized, like a cicatrix, and thus produces more or less considerable stenosis of the cardiac orifice, and consequently death from impeded circulation. The endocarditis which occurs in puerperal conditions produces, on the contrary, an exuberant vegetative tissue, the organization of which is impossible, and its detritus may carry infection throughout the entire organism. According to Lancereaux this new species of endocarditis is especially localized in the valves of the aorta, and attacks, by preference, those who have been poisoned by paludal miasm. This endocarditis is anatomically represented by tumefactions located at the valves of the aorta, and sometimes at the mitral valve, with prominent vegetations, free or covered by fibrinous deposits. Histologically, they consist of small, round, embryonic elements, formed at the expense of the connective tissue. When these vegetations undergo a granular fatty degeneration, aneurisms, lacerations, ulcers of the valves, and molecular detritus are formed, which may give rise to embolisms, etc. The symptomatology does not differ from that of the other alterations of the aortic valves; a differential diagnosis is, therefore, almost impossible. A double souffle, with its greatest intensity at the base of the heart, and prolonged to the aorta, and throughout the thorax, is the constant sign. It coincides with cardiac hypertrophy, hepatic hyperæmia, without œdema of the extremities, and with characteristic splenic engorgement. A few slight chills, a paroxysmal fever, vomiting and diarrhœa, anorexia, and dejection are, according to Lancereaux, the general symptoms which assist most in the diagnosis. The adynamic character of the phenomena, the lividity and the pallor, without convulsions, are the most important complements. Its course is more rapid than that of rheumatic endocarditis. A little more than a year suffices for the evolution of the disease, and the fatal termination is not caused by any impediment to the circulation, but rather by an intoxication of the blood; hence the fever and the other phenomena not observed in the former. The prognosis is, therefore, very grave, for therapeutics cannot prevent the softening and the detachment of the vegetations. The septiciemic phenomena should be combated with tonics and antiseptics. Quinine betters the symptoms decidedly.—*Bouvar, de Sci. Med. and Lo Sperimentale*, Jan., 1875.

NEUROSIS OF THE JOINTS AND THEIR TREATMENT.—

The following summary of the subject is, from a paper by Moritz Meyer, of Berlin. Cases of painful affections of the joints, as described by Sir Benj. Brodie, some fifty years ago, under the name of "Hysterical Affections of the Joints," and which often simulate inflammation of those parts, have recently received attention from Stromeyer and Esmarch. The seat of the disease is in the small branches of sensitive nerves supplied to the capsule of the joints, and the integuments in the neighborhood. It is marked by pain, often of such a degree as to prevent the use of the joint, and to result in its fixation in a certain position, being often the only cause of an immobility which lasts for years or for life. According to Berger, it may originate in nervous subjects without any direct cause, while in healthy persons it is often the result of mental or emotional causes, of trivial or more serious injuries of the joints, or of irritations reflected from the gastric, urinary, or genital organs. Its discrimination from an inflammatory affection, especially when it is ascribed to a traumatic cause, is of great importance, particularly in reference to the treatment applicable to one or the other case. The following points will aid in differentiating it from affections which it resembles. 1. Nocturnal pain is commonly absent. 2. The joint will be found more sensitive to slight movements and handling than to rougher manipulation. 3. Œdema and swelling of the skin and cellular tissue are often observed to appear and then vanish. 4. There are sometimes periodical changes in the temperature of the affected joint. 5. The muscles are relatively but little shrunken in spite of long periods of absolute rest. 6. There is great want of agreement between the trivial objective symptoms and the severe complaints of the patient. 7. It is often possible to bend the joint without complaint of pain, when the patient's attention is distracted. A spontaneous cure is not unfrequently wrought by a variety of causes working through the mind or passions, and where the affection is of reflex origin, by the cure of the primary disease. Stromeyer and Esmarch have attained the best results by a general tonic management, supplemented by the kneading and passive motion of the affected joints, and they specially emphasize the active use of the limb. To these remedial measures Meyer adds the recommendation of a strong induced electrical current, to be applied directly to the painful joint, for which he claims anæsthetic and anodyne effects, as well as an excellent sedative effect upon the mind of the patient. Meyer appends an account of four cases observed by himself in which the results of faradization are well illustrated, and also one of Esmarch's, where he and Stromeyer proved most strikingly the efficacy of the treatment by active exercise.—*Sitzungsbericht der Berliner med. Gesellsch.*, 1874.—*Allg. med. Central-Ztg.*, Jan. 13, 1875.

IMPROVEMENT IN THE ELASTIC TOURNIQUET.—At a recent meeting of the *Glasgow Pathological and Chemical Society*, Dr. David Fonlis showed an instrument he had devised for fastening the ends of the elastic cord used as a tourniquet in Esmarch's method. It consists of two connected metal tubes: one to hold the band, the other to catch it at any degree of tension. To apply it, the band is stretched across the limb, the catch being in the middle; the ends are then passed under and around the limb, and brought up and slipped into the slit of the upper tube while on the stretch. The expansion of the India rubber, on relaxation, fixes the ends finally in the catch. To remove the pressure the ends are stretched, and, while thus narrowed, are lifted out of the catch.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 13, 1875.

THE PROPOSED AMENDMENT TO THE PRESENT MEDICAL LAW.

A NEW Medical Bill has been presented to the State Legislature during its present session, which may be considered as an amendment to the law now in force regulating the practice of medicine. In another column we publish the Bill in full, and would direct the attention of our readers thereto. There is certainly plenty of room for improvement in the present law, but any one who studies the provisions of the new one proposed will hardly be assured that any great advance has been made. On general principles we are opposed to medical legislation; we have had too much of it already, and it is a matter of congratulation that the profession is beginning to find it out. However, it becomes us to be reasonable, and discuss every matter from an impartial stand-point. Every proposed law affecting either directly or indirectly the interests of the profession deserves consideration.

In a previous number we alluded to the deficiencies in the present law regulating the practice of physic in this State. The proposed amendments to this law, with one or two exceptions, really amounts to nothing, and may in the end tend to multiply the difficulties and swell the perplexities under which we already labor. As is commonly the case with all laws intended to prevent the spread of quackery, the onus of its support falls upon the profession. The censors of the different County Societies have to perform the greater part of the work, and are more or less responsible for the infliction of the penalties. One of the provisions of this new bill makes it obligatory on the President and Secretary of each County Society throughout the State to cause a written notice, duly signed, "to be served personally upon persons practising medicine or surgery residing in the county in which such society is located." This of itself is a great labor, entailing many responsibilities, and for which no remuneration is to be expected. As a matter of justice, we question the right of any State to press into its service, for its own benefit, one

set of men more than another. What right has the government to compel any private citizen to perform public duties? It strikes us that our Legislators should first consult the wishes of the profession on the subject, before taking upon themselves the responsibility of passing such a law.

Not only are the County Societies compelled to notify those practising in their respective districts, but the censors are commanded to examine all such as may have neither diploma nor license. This is another extraordinary provision, which, although it is already in force by the present law, is far from being just to the profession. But this is, perhaps, one of the penalties of an eagerness on our part, in times gone by, to volunteer our labors so gratuitously to prevent the spread of quackery. We have heretofore made our lawgivers believe that we were so personally interested in such laws, that there was so much benefit to be gained in their enforcement, that we were only too willing to do everything toward that end.

Although in the proposed amendment the District Attorney is the prosecuting power in case of violation of the law, the society is, after all, compelled to be an accessory to any legal action. Here again we have the old story. As a profession we do all the work to fulfil a law, and then are compelled to shoulder the responsibility in enforcing it. The ostensible object is to prevent the people from becoming the victims of quackery. By carrying out this object who are most benefited—the people or the profession? It is perfectly proper for the State to look to the profession to decide upon the qualification of men to practise an art, but it is equally proper that all who perform such labor should be suitably remunerated.

As the case stands at present, there are not enough redeeming features in the proposed amendment to make it necessary to add another page to our statute books, or to make it worth while even to modify the obnoxiousness of the present law by attempting to make it a little more consistent. We should much prefer to have it as it is, hoping for the speedy arrival of the time when it shall be repealed altogether, and the profession placed on its former footing.

THE ARMY STAFF RANK BILL.

CONGRESS has adjourned. The Chairman of the Military Committee of the Senate, Mr. Logan, of Illinois, refused to allow anything to be done with the Army Staff Rank bill. This extraordinary procedure deserves notice in connection with the numerous petitions from the medical organizations all over the country. There is little doubt, however, that the bill would have passed both the House and the Senate, if it could have been brought before them. We shall take occasion at some future time to discuss the situation more in detail. Neither the profession nor the medical staff of the Army need be disheartened at the defeat, as such was insured more by political trickery, than by any failure on the part of the advocates of the bill, to do everything calculated to bring about the much desired result.

MARINE HOSPITAL SERVICE.

Our readers will be pleased to learn the fate of the bill for the increase of efficiency in the Marine Hospital Service, which has been noticed several times in these columns. When the bill was placed on its passage in the Senate, an amendment was offered striking out Sec. 7, which provided for permanent staff organization, and that amendment being adopted, the bill was then passed. Just before adjournment the House also acted favorably upon the bill, and, with the approval of the President, it became a law. The office of the Chief of the Service only was raised out of the political arena. The Supervising Surgeon-General, as the new title stands, will hereafter be a commissioned officer. It is particularly gratifying to us to notice that in the final action upon the bill, the salary of this gentleman was restored nearly to the original figure.

The present Supervising Surgeon, Dr. John M. Woodworth, having made the office what it is, will of course receive the permanent appointment as his reward, which indeed he well deserves. Practically, he had already, under the Civil Service rules, secured the advantages of the commission for the staff of the Marine Hospital Service, no one having been allowed to enter the service since December, 1873, except upon the recommendation of a board of medical examiners. Now, that the principle is firmly established in the appointment of the chief, we shall look for a steadfast improvement in this important branch of the public service, and we bespeak for Dr. Woodworth and his earnest confidés the cordial support of every member of the profession.

Reviews and Notices of Books.

SURGICAL EMERGENCIES, TOGETHER WITH THE EMERGENCIES ATTENDANT ON PARTURITION AND THE TREATMENT OF POISONING. A Manual for the Use of General Practitioners. By WILLIAM PAUL SWAIN, F.R.C.S., Surgeon to the Royal Albert Hospital, Davenport. Philadelphia: Lindsay & Blackiston. 1874. 12mo, pp. 183.

THE number of emergencies which constantly arise in the practice of every family physician is always considerable, and so much depends upon his readiness to meet them, that too much importance cannot be attached to their study. The little work before us is one which helps to supply the text for such a study, and so well does it fulfil its design that it is hard to distinguish its different points of excellence. The arrangement of the subjects is very judicious, and the descriptions of the various operations are graphic, terse, and intelligible. Of course all the directions which are laid down for the treatment of the different accidents are to be found in the larger text-books; but to any one who is not a practical surgeon, they do not make such an impression upon the mind as when arranged by themselves in a small hand-book. This is one of the recommendations of such volumes to the general practitioner, who, although he is not expected

to be a surgeon, is constantly liable to be called in many of the most trying cases in which the prompt exercise of the right sort of knowledge may be the only means of averting sudden death. It is needless to particularize the number of such emergencies, as they at once suggest themselves to every one in active practice. We do not even pretend to catalogue the large number which are referred to in the work before us, but shall only allude to a few of the most important. In the injuries about the head we have the different methods of treatment given as applicable to each case. The operation of trephining, probably the most important one that is called forth by an emergency is very well described. In severe epistaxis Bellocq's canula is recommended, and its mode of application illustrated. The same may be said for the India-rubber bag, preferred by many surgeons. In fracture of the spine great stress is laid upon the avoidance of all motion of this part at the time of accident. As regards the wounds of the eye by foreign bodies, every one of the simple operations is described. The chapter on injuries of the œsophagus, and the choking from foreign bodies lodged in the tube, are judiciously treated, and the method of using the different probangs is given. The author has, however, omitted reference to a very ready remedy for ordinary choking (*i.e.*, when the foreign body is not impacted), *viz.*, the smart slapping of the back. But it is to be presumed perhaps that every physician is already well acquainted with it. Laryngotomy and tracheotomy are two of the very important operations which we are sometimes compelled to perform at once. In the descriptions of these, as well as those for hernia, the author has fully appreciated the wants of the practitioner. Catheterization is another subject well treated, while ample space is given to the description of the operation of aspiration, which of late has become so fashionable. Fractures and dislocations also make up a part of the work, which, although well enough in their place, are not as important as those sections which are devoted to the other subjects. Notably, in this latter connection, we may mention the chapters devoted to the emergencies of parturition and poisoning. As a whole, this work is well calculated to fulfil the design for which it was written, which is the best of all recommendations. It is well illustrated and well printed.

PULMONARY TUBERCULOSIS. By ADDISON P. DUTCHER, M.D. J. B. Lippincott & Co., Philadelphia. 1875, pp. 380.

DR. DUTCHER has written a work, in thirty-nine chapters, on Pulmonary Tuberculosis. He tells us in his preface that he claims no special originality for his work, but thinks it will be none the less valuable to the profession. Duty, he remarks, prompts him to the work, and to contribute his mite to the advancement of medical science. We think that Dr. Dutcher does himself injustice; his work is original to a remarkable degree. He has constructed one of the most curious pieces of patchwork that we have ever seen. His ingenuity in selecting from various authors theories which are obsolete, and in twisting and confusing the facts which are to be found in every text-book, is something truly remarkable. We can compare it to nothing but to a newspaper reporter's rendering of some scientific discourse, preserving all the names and omitting all the sense.

The pathology seems to be taken from Lebert. It states, in its most naked form, the old doctrine of tubercle corpuscles.

The description of the physical signs seems to be

the result of reading Dr. Flint's work, without understanding it. The account of the general symptoms and the directions for treatment are the least objectionable features in the book.

The fine writing and the moral reflections are, without doubt, all Dr. Dutcher's own. Here is a sample: "There is a chastened and holy pleasure in administering to the wants of one who is standing, as it were, upon the verge of the better land. The silent chamber where the messenger of dissolution waits for his expiring prey, is often the gateway to eternal life. And oh! how often, as I have felt the last throb of the pulse, heard the last breath, and seen the last flash of the eye, as the soul escaped from its earthy tenement, have I been reminded," etc.

From this short extract it may be seen that the medical patchwork is held together by the most ornate reading. But the worst feature of the book is, that it is impossible to read it without feeling that it is intended, not for the medical, but for the general public; not as a contribution to medicine, but as a business advertisement.

SYPHILITIC LESIONS OF THE OSSEOUS SYSTEM IN INFANTS AND YOUNG CHILDREN. By R. W. TAYLOR, M.D., etc. New York: William Wood & Co. 1875. 8vo, pp. 179.

THE author of this essay is already favorably known by his contributions to our knowledge of that rare manifestation of syphilis, *daetylitis syphilitica*, and other subjects connected with syphilis and diseases of the skin. The lesions which he now analyses have generally, as it appears, been confounded with those of rickets. Their comparative frequency, together with the somewhat rare occurrence of well-marked rickets in this country, should have led to the early recognition of their nature by American observers; but the demonstration of their origin in syphilis was reserved for Wegner, of Berlin. As Wegner's article, however, dealt wholly with their etiology and minute anatomy, and as the contributions of others have been only fragmentary, a systematic consideration of them from a clinical point of view was still needed. The essay before us fills this gap very thoroughly and satisfactorily.

Dr. Taylor's work is founded upon an analysis of sixteen cases, which were closely and carefully observed by himself, and upon forty-eight cases recorded with more or less completeness by others, including twelve by Wegner, twelve by Waldeyer and Köbner, seven by Parrot, three by Bärensprung, two by Fournier, two by Bulkley, and one each by Roger, Curtis Smith, Bertin, Archambault, Putegnat, John Morgan, Ranvier, Bargini, Valleix, and Guéniot. Twelve of the author's own cases occupy twenty-six pages in their recital, being given with great fidelity to detail; the remaining four were observed during the progress of the work. Of the other cases, which take up thirteen pages, some are given *in extenso*, while others are merely outlined, the pathological minutiae being reserved for consideration in a subsequent portion of the book.

The comparative frequency of osseous lesions in the early period of infantile syphilis is exemplified by the fact that two of Dr. Taylor's patients were sisters, of whom the elder was infected from the younger. There are other points of interest apart from the mere study of the osseous lesions; for instance, in one case the mother imputed her child's trouble to vaccination, although she herself had been under treatment for syphilis.

The bony swellings, which constitute the lesions

more particularly described by Dr. Taylor, always occur in the case of the long bones, at the junction of an epiphysis (generally the distal one) with the shaft. This localization of the morbid action the author refers to the greater intensity of the normal processes of ossification going on in those portions of the shaft and epiphysis which adjoin each other. They end either in resolution or in degenerative changes, the accidental occurrence of diastasis being occasionally met with, in which case there is a condition requiring treatment as for fracture. In one case, reported by Putegnat, degeneration of the swelling was followed by dislocation of the head of the femur, a fact which, as the author remarks, shows the importance of the early recognition of this syphilitic lesion of the bone, and the necessity of prompt and efficient treatment.

Six sections of the work (thirty-seven pages) are devoted to a detailed description of these lesions. These descriptive details are very carefully given, and are of great importance, although they might strike the reader as being unnecessarily prolix. Doubtless greater accuracy is secured by the plan of a separate account of the features of these swellings for each particular bone which they have been observed to invade, although terseness and vividness are thereby necessarily more or less sacrificed.

In the thirty-five succeeding pages the clinical history of these manifestations is still further traced as regards the development, course, and distribution of the bony swellings; their effects upon the integument and upon the joints; the degenerative changes which may occur in them; the accident of the separation of an epiphysis from the shaft of a bone; the symptoms induced by the swellings; the periostitis of the hereditary syphilis of infants; the effects of the osseous lesions upon the ultimate structure and shape of the bones; the period of the disease in which the lesions occur; the question of the development of similar lesions in acquired infantile syphilis; their value as an index of the intensity or activity of the disease; and the condition of the disease in the mothers of the affected children—which considerations, it will be seen, very thoroughly cover the ground occupied by the pathology of the bony manifestations of syphilis in children. The matter is ample, and the manner of its treatment is satisfactory.

The succeeding section treats of the pathological histology of these bony swellings, and the author has evidently taken great pains with this portion of his subject. The result is a compact and admirably clear description. In a short section on the relations between syphilis and rickets, Dr. Taylor is equally happy, showing, by a very vivid line of argument, that rickets cannot be directly due to syphilis, although the syphilitic cachexia may lay the foundation of those errors of nutrition upon which the rickety condition depends.

The diagnosis of these affections is fully and judiciously considered, which involved the consideration of many lesions of similar appearance, but not dependent on syphilis.

The treatment which the author prefers consists mainly in the use of the corrosive chloride of mercury, in combination with iodide of potassium. This treatment should be kept up for a considerable length of time, taking care to so manage it as to avoid producing derangement of the gastro-intestinal functions; judicious auxiliary measures, chiefly designed to improve the general condition, are also mentioned, together with the local treatment called for by ulcerative degeneration, and the surgical management of diastasis.

The remainder of the volume is principally devoted to a comparison of the characters of these lesions with those of certain other osseous affections, syphilitic and non-syphilitic.

We earnestly commend the work to our readers, as being a very creditable digest of facts which have been observed by the author, and a critical analysis of those which have been recorded by others. Dr. Taylor's style of writing is, in general, simple and clear, and his concise way of putting facts will go far to make the subject readily understood. In very many instances he uses wonderfully expressive words; but, on the other hand, the book contains many phrases which may perhaps be considered inelegant. Prominent among these, we may mention the expressions, "mixed treatment," "five drops of the mixed treatment," "clinical cases," "twice thicker than usual," and "clinical practice." There is also an occasional crowding together of adjectives before a noun, which is foreign to the genius of the English language. Grammatical and typographical errors are few in number.

Among the latter we notice, that in the section devoted to casuistics, there is a lack of uniformity of style in numbering the cases quoted from other observers—some being numbered in Roman and some in Arabic numerals, while others are not numbered at all. The book is well printed, on heavy paper, and its general appearance is very creditable to the publishers.

All things considered, we must congratulate Dr. Taylor on his admirably thorough and systematic elaboration of a department of pathology which, notwithstanding the fragmentary contributions of others before him, is now for the first time presented to the profession in a finished form.

CLINICAL LECTURES ON DISEASES OF THE NERVOUS SYSTEM. By WM. A. HAMMOND, M.D., Professor of Diseases of the Mind and Nervous System in the University of the City of New York, etc., etc. Edited by T. M. B. CROSS, M.D., Assistant to the Chair of Diseases of the Mind and Nervous System in the University of the City of New York, etc., etc. *Nihil desperandum.* Published by D. Appleton & Co., No. 551 Broadway, New York.

This book is made up of Clinical Lectures, delivered at the New York Hospital for Diseases of the Nervous System, and at the Bellevue Hospital Medical College. It contains 289 pages, which are divided among different subjects, twenty in number. In general, there is a fair statement of the commonly accepted theories upon the etiology and pathology of the diseases considered. The editor has done his work very well, and the book is among the number to be read by those who wish to read everything that is written upon diseases of the nervous system.

HOW CHILDREN'S DISEASES ARE TREATED.—It seems as if Bismarck must have set the following stories in circulation as aids in his warfare upon the abuses of the Church. It is related by Dr. Kruger in the *Bayer. Aertzl. Intell. Blatt.*, that among the population of Schongau, in Upper Bavaria, the vomiting and purging of children artificially reared is thought to be a curative effort of nature. When a child is very sick they hang up his soiled shirt in a neighboring shrine, and from the day the pilgrimage begins the little victim is neither to have medicine, to be bathed, or have his clothes changed. In Munich also many children are treated with "Consecrated Life and Death Powders," purchased at a certain convent.—*Rundschau*, Dec. 1874.

Reports of Societies.

ACADEMY OF MEDICINE.

Stated Meeting, Feb. 18th, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

THE paper for the evening was upon "Reparation of Brain-tissue after Injury," by John P. Gray, of Utica, New York.

In the absence of Dr. Gray, the paper was read by Dr. S. Oakley Vanderpoel.

It consisted mainly of the history of cases in which severe injury to the skull had been sustained.

The first case was a lad ten years of age, "The boy Galli," who had sustained a severe fracture of the skull on the side of the right frontal bone. No unconsciousness followed. The sides of the face at the time of the injury were smeared with brain-substance, and when a portion of bone was removed from the wound, a portion of brain-substance was forced through the opening. The convolutions of the brain were apparent. At different times during the process of the case masses of the size of a pigeon's egg, and a hen's egg, were removed, either with the knife or ligature. No microscopic examination of the masses removed was reported. A free opening was maintained for the discharge of pus and serum, which at times was considerable. On the sixty-eighth day all the general symptoms had subsided. Slight pressure was made upon the then protruding mass, and in a few days it returned within the cranium. On the ninety-eighth day the wound was nearly healed over.

The child finally recovered entirely, but was deaf. The case was under the personal care of Dr. Hutchinson.

The second case reported was that of a soldier, forty-one years of age, who was wounded in the head by a Minié ball. Forty-eight pieces of bone were removed, but the report did not state whether there was any loss of brain-substance. The wound healed, and for five years he remained in good health.

His general health became impaired in 1868, and finally melancholia was developed. He was received into the asylum, and, after a few months, discharged cured. In 1873 he was again admitted to the asylum, and fourteen months after his admission was profoundly melancholic, and finally died.

Autopsy.—No attempt had been made at bony reparation. The arachnoid and pia mater were renewed (at least were present), and no traces of the injury could be detected in the brain-substance. The convolutions were fully outlined, and resembled the convolutions upon the unaffected side of the brain.

The case of Anthony Gaige was referred to, who had a tamping iron driven through his brain, by the premature explosion of a blast. (Vide *American Journal of Medical Sciences* for July, 1850. Mention is also made of the case in "Dalton's Physiology.") Three cases of attempted suicide were mentioned in which the pistol-ball entered the skull and remained. In each case pressure was exercised over the wound during the progress of reparation.

DR. BUCK reported cases in which there had been a loss of brain substance, followed by recovery of the patient. The patients, apparently, were completely restored, for they were in good health and engaged in active business after their recovery.

DR. CARO related the history of a case in which the

man fell from a scaffolding and struck square upon his feet, was immediately paralyzed, and fell over. The patient was subsequently trephined, and about a tablespoonful of pus and blood was removed. Symptoms immediately relieved. Protrusion of brain matter followed. It was tied off. The patient made a good recovery. Has been in good health since his recovery, and only has a slight defect in his memory.

Dr. BUCK regarded the protrusion in these cases of so-called hernia cerebri as a compensating process to make room for the suppuration. He had also noticed that the incision of the brain matter was not attended by painful sensations.

Dr. PEASLEE was of the opinion that it had not yet been proved, unless by the cases of Dr. Gray, that the convolutions of the brain have actually been reproduced after a certain amount of brain substance has been removed. It has been well settled that nerves have been reproduced. If the protrusion is a protrusion of newly-formed brain substance, he could not see the propriety of removing it. There would be no danger of the formation of too much brain tissue, but probably the apparent redundancy would be absorbed, and finally all be returned to the cranial cavity. It seems to have been the opinion of Dr. Gray, regarding the mass of substance extruded in the case of the boy Galli, that if it had been left undisturbed it would finally have disappeared within the cranial cavity.

Again, with regard to the process of repair, is it necessary, in order that brain substance be repaired, that solution of continuity shall first be filled up with connective tissue, and then within the meshes of that, brain substance be formed? Dr. Gray refers to finding a large amount of connective tissue present.

If we can reason, *à priori*, we should expect that brain tissue would be restored from necessity. All the other tissues of the body are in keeping with the law of necessity restored, and certainly of all tissues in the human body, brain-tissue is most needed. Unless we can say that one hemisphere is sufficient to carry on all the functions of the brain, we must say, in certain cases, that there is a restoration of brain substance. PROF. DALTON remarked that the direct point with regard to the paper was concerning the proof it furnishes with reference to the actual restoration of brain substance after its destruction and removal. This was the first point of interest. In the case of the boy Galli, it was very certain, from the record, that a portion of brain substance had been actually removed. Now the question arises was that portion reproduced? Dr. Dalton said that he felt obliged to acknowledge that he did not see the direct proof of this reproduction. A large quantity of new tissue was produced and removed by the knife, but the paper did not state that this newly formed substance had been examined by the microscope and found to be composed of true brain-tissue.

If the successive protrusions, sometimes as large as a pigeon's egg, or even a hen's egg, had been thus examined and found to be composed of brain-tissue, then we could say positively that the substance of the brain had been reproduced. But at present we can hardly assert this as being directly proved, and are rather left to infer it from one item in the record—namely—that the boy recovered with a complete or almost complete restoration of his mental and bodily faculties. But he was not so sure that this could be relied on as absolute proof of actual restoration of brain substance; for it is believed by many that the two hemispheres are capable of acting each for the other, and, so far as we understand their physiological

action, we cannot look upon it in any other light. A simple recovery of the mental faculties, after a portion of brain substance has been removed, does not therefore prove a regeneration of the brain substance.

In the second case, that of the soldier, the ball was imbedded in the brain substance. There is nothing, however, in the record to prove distinctly that there was any great actual loss of brain substance. It is not very easy to understand how a ball, sent with sufficient force to penetrate the skull and become imbedded within the brain substance, could do so without destroying more or less of it; but, at the same time, it would not seem impossible for a ball to penetrate the skull and make room for itself by forcing the brain matter away in some other direction, provided room were afforded by the opening of the cranial bones. He did not think, therefore, that we could say positively, even in this case, that the brain-tissue had been reproduced. We know that certain mental faculties have been sometimes restored after injuries of the brain substance; but in order to say with absolute positiveness that the recovery of the mental powers in any case of this kind was complete, the reporter ought to have known the individual for several years, and should be personally familiar with his character. Suppose for instance, that a man is simply a little more irritable in disposition after such an injury than before; the reporter of the case might overlook such a fact entirely, while the friends of the patient who were intimately acquainted with him might be well aware of the change. In this way a physician might be led to say, in general terms, that his patient had recovered all his mental faculties; while the friends might notice many things about him which would indicate a permanent change in the man's mental condition.

There is certainly no inherent improbability in the supposed regeneration of brain substance. It is known that nerves may be reunited after division and even after the removal of a portion of their substance; but the cases in which this has been successfully done are nearly all those of very young animals.

The operation as a physiological experiment will usually not succeed in animals that have attained their full growth. With regard to the restoration in the human subject, of a divided nerve which has been simply cut across by a clean incision, it seems to be generally acknowledged by surgical practitioners that as a matter of fact, this does not very frequently happen. When a nerve, either sensitive or motor, is divided in one of the lower animals the first effect of the section is of course abolition of function. After that a degeneration of the nerve-fibres takes place beyond the point of injury, and that is a comparatively long process.

In the course of four or five days after section a motor nerve loses its irritability. That condition generally lasts about six weeks; then the power of motion becomes gradually restored, a similar process occurs in the degeneration and restoration of sensitive nerves. When the operation is successful the final result is a restoration of the nervous functions, but only after a considerable interval of time.

Recently doubt has been thrown upon many cases previously reported, and it is said that an accurate examination fails to show in most of them complete evidence of the restoration of nervous function.

When a practitioner reports cases in which sensation and the power of motion are said to have been restored in the paralyzed parts, he is not always careful to distinguish between the restored sensation which strictly belongs to the divided nerve, and what is called *supplied sensation*, which may come in play in conse-

quence of the activity of other nerve-fibres derived by anastomosis from adjacent branches when sensibility is found to be restored to a paralyzed part within twenty-four hours after the division of its nerve, this sensibility is without doubt supplied by some other nerve, which has not been divided, but only temporarily paralyzed by the shock of the injury. If the examination for sensibility in these cases be made rather roughly, as by means of the points of a pair of ordinary dressing forceps, or by simply pinching the skin or by the galvanic current, the shock to the sensitive papillæ which are paralyzed is very apt to include papillæ at a little distance supplied by fibres of a nerve which has not been injured.

The sensitiveness of the papillæ is such, and the anastomosis is so abundant between adjacent branches of certain nerves, that the examination must be made with the greatest care in order to arrive at reliable conclusions.

There is the same difficulty with regard to regeneration of motor power. These conclusions of recent observers certainly are sufficiently plausible to make us take great care in stating that sensation and motion in any instance have been completely restored beyond the point at which a nerve has been divided.

If such a nerve as the sciatic be divided, and if afterwards motion and sensation be restored to the leg or foot, then there could be no doubt of the regeneration of the nerve-fibres; but the cases of this kind which have been reported are mostly those in which the median or ulnar nerve, or one of the branches of the fifth pair, or one of the cervical nerves have been divided, and in those cases there must be great room for doubt with regard to restoration of sensation and motion independently of anastomosis.

It seems to be also true that a loss of function after injury of the brain substance does not always have the significance we might at first attribute to it.

Suppose that a portion of the brain is damaged, and that this injury is followed by loss of sensibility in a particular part. This does not prove that the nerve-fibres which have been cut across are conductors of sensibility; for the reason that any injury inflicted upon the nerve-centres made by sympathetic irritation produces signs which are not directly due to destruction of the nerve tissue, and the evidence of this is that the power of sensibility in such cases will often return before the nerves have been regenerated.

Correspondence.

THE GALVANO-CAUTERY IN THE TREATMENT OF HYDROCELE OF THE NECK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR.—The following case, almost an exact duplicate of the one detailed in the No. of THE MEDICAL RECORD of August 15, 1874, p. 425, as cured by Dr. Amussat, may be of equal interest. The patient, Mrs. Catherine Ennis, aged 70 years, general health feeble, had for fourteen years been the subject of a sero-sanguineous cyst of the neck. This, as described by her, had first appeared in the middle line of the neck, just below the larynx, thence had developed prolongations upon either side of the neck. Recently the left lobe had increased in size much more rapidly than the rest of the cyst. In July, 1874, when she first came under my observation, the tumor extended upon the left side from the

angle of the jaw above to the sternum below, overlapping the latter to the extent of an inch and a half; filling up the anterior triangles of the neck. The prolongation upon the right side was not more than one-third the size of its fellow-cyst, and when tapped yielded about 8 oz. of sero-sanguinolent fluid. Injected the cyst with a solution of iodine and iodide of potassium. Same treatment repeated in November. As the result of the first injection the tumor was reduced to about one-third its original size. No special benefit resulted from second injection.

January 8, 1875, the sac, having been emptied of its fluid contents, was cauterized as thoroughly as possible by a platinum wire, which had been made to traverse its long diameter, and connected with the galvanic battery. The wire was then withdrawn. This application of the galvano-cautery was made by Dr. George R. Fowler, of Brooklyn. The inflammatory reaction resulting was not sufficient to prevent the patient from pursuing her ordinary household duties. For three or four weeks the sinuses left by the cautery discharged freely.

At the date of this report, about seven weeks from the time of the operation, the sinuses have entirely closed, and the only trace of the tumor remaining is a slight thickening, from inflammatory deposit, which can still be felt in the site of the old sac.

LEWIS S. PILCHER, M.D.

Medical Items and News.

AMENDMENT OF THE LAW REGULATING THE PRACTICE OF MEDICINE.—The following proposed amendment to the present law regulating the practice of medicine in the State (Act passed May 11th, 1874, and published in THE MEDICAL RECORD, of Nov. 2d) has recently been presented by Mr. Laning:

Section 1. Every person who shall hereafter practise medicine or surgery in this State, unless such person be authorized to practise by a license or diploma from some chartered school, medical society or State board of medical examiners, of some one of the United States, shall obtain and is hereby required and directed to obtain, a certificate from the board of censors of some one of the medical societies of this State, either of a county medical society of the county where such person shall at the time reside, or of a State medical society, or from the State board of medical examiners, which shall certify that the board of censors of such society or the State board of medical examiners have examined and do find the person named in such certificate, and to whom the same shall be issued, qualified to practise all of the branches of the medical art mentioned therein; which certificate shall be tested by the signatures of the censors or examiners holding the examination and the seal of such society. And the person to whom such certificate, license or diploma shall be granted shall, before he shall practise medicine or surgery in this State, cause such certificate, license or diploma to be recorded in the office of the clerk of each county in which such person shall from time to time reside. And the clerks of the several counties of this State shall procure and keep suitable and proper book or books, in which he shall record such certificates tested as aforesaid, and such licenses or diplomas whenever presented to be recorded, upon the payment to him of the same fees as required to be paid for re-

ording conveyances of real estate, and shall index, in alphabetical order, the names of the person to whom such certificate, license or diploma shall be granted, noting therein opposite to the name indexed the book and page where such certificate, license or diploma is recorded, the date of the instrument and of the recording of the same.

Section 2. The board of censors of the medical society of each county in this State, shall cause a printed or written notice, signed by its chairman and secretary, to be served personally upon every person practising medicine or surgery residing in the county in which such society is located, except those who have caused to be recorded in such county such a certificate, license or diploma as described in section one, as amended, of the act hereby amended, directing attention to this act, and appointing in said notice a time and place, not less than twenty days nor more than thirty days after the service of said notice as aforesaid, at which said board of censors will convene to examine such persons as shall present themselves to be examined for such certificate as aforesaid. And in case the person upon whom such notice shall have been served as aforesaid, shall not appear for examination before said board of censors at the time and place named in said notice for the convening of said board, nor produce to said board a certificate of the county clerk of said county of the recording of such certificate, license or diploma as aforesaid, such persons shall thereafter be subject to all the provisions, liabilities and penalties prescribed by this act for any violations thereof.

Section 3. It is hereby declared a misdemeanor for any person to practise medicine or surgery in this State who shall not cause to be recorded in the county where he shall reside such certificate, license or diploma as described in the foregoing sections of this act, either prior to or within twenty days after the time named for the convening of said censors, in the notice prescribed in section two as amended of the act hereby amended, or who shall practice under cover of the record of a certificate, license or diploma fraudulently or illegally obtained; any person found guilty of such misdemeanor shall be punished for the first offence by a fine of not less than fifty dollars nor more than one hundred dollars, and for any subsequent offence by a fine of not less than one hundred dollars nor more than five hundred dollars or by imprisonment in the county jail not less than thirty days, or by both such fine and imprisonment.

Section 4. It shall be the duty of the society, whose board of censors has caused to be served the notice required to be served as aforesaid to cause information to be given to the district attorney of the county in which such society is located of any violation of this act; and it shall be the duty of such district attorney to bring all cases of the violation of this act of which he shall receive information, before the grand jury in such county, and to prosecute the same.

Section 5. All fines collected under the provisions of this act shall be paid over by the district attorney to the county treasurer of such county.

CONGRESSIONAL APPROPRIATION FOR THE NAVAL BUREAU OF MEDICINE AND SURGERY.—Necessaries for vessels, \$30,000; repairs of naval laboratory, hospitals, and appendages, \$20,000; civil establishment at naval hospitals and laboratory, \$35,000; contingent expenses, \$25,000. Total, \$110,000.

MEDICAL AND DENTAL GRADUATES.—The Medical Department of Nashville and Vanderbilt Universities has just graduated fifty-eight students. The Medical

College of the University of Wooster, thirty; the School of Medicine in the University of Maryland at Baltimore, fifty; the College of Physicians and Surgeons, at Baltimore, thirty-nine; the College of Dental Surgery, in the same city, seventeen; Yale, seven; the College of Physicians and Surgeons, Med. Dep. of the Syracuse University, eleven, one of whom was a female; the N. Y. College of Homœopathy, thirty-nine; the N. Y. College of Dentistry, sixteen.

THE UNIVERSITY OF LEYDEN recently celebrated its three hundredth anniversary, and numerous honorary degrees were awarded; among others the degree of Doctor in Medicine was conferred upon Herr Bunsen, of Heidelberg; Mr. Darwin, of London; Mr. Milne Edwards, of Paris; and Mr. Spencer Wells, of London.

THE ENGLISH NAVAL MEDICAL SERVICE.—The following regulations have received the approval of the Queen, on February 4:

"1. That surgeons on entry shall have the same relative rank as paymasters, chief engineers, and naval instructors—namely, shall rank with lieutenants under eight years' minority, and shall have uniforms corresponding to such relative rank.

"2. That staff-surgeons shall be denominated fleet-surgeons, and staff-surgeons second class simply staff-surgeons; the distinction in rank between these two grades to be denoted by a small difference in the uniform.

"3. That inspectors-general shall be compulsorily retired at the age of sixty on £2 per day, provided they shall have completed the period of service now required to entitle them to the maximum half-pay of their rank.

"4. That deputy inspectors-general shall be compulsorily retired at sixty, if in the first six of their rank, at 33s. per day, others at 30s. per diem, provided that they shall have completed the period of service now required to entitle them to the maximum half-pay of their rank.

"5. That fleet-surgeons and staff-surgeons shall be placed on the same scale of retirement as chaplains and naval instructors, secretaries, paymasters: that is, the maximum to be £450 per year, instead of £400.

"6. That any fleet-surgeon shall have the option of retiring after twenty years' full-pay service in all ranks, at 15s. per day, and after twenty-five years' service at 21s., subject in each case to our approval; but that of those now on the list no more than ten shall retire under this clause in each year (the officers having the option according to seniority), unless we should approve (with the consent of the Lords Commissioners of your Majesty's Treasury) of a large number so retiring.

"7. That of the medical officers to be hereafter entered all shall have the option of retiring, subject to our approval in each case."

STATUES OF SIMPSON AND LIVINGSTONE are to be erected in Edinburgh in the East Princes Street Gardens, near the Scott monument.

DR. BARNES' successor in St. Thomas' Hospital is Dr. Gervis.

A FAINTING MIDWIFE.—The sub-editor of the *Union Médicale* relates that a young lady belonging to one of the most respectable families of Paris refused, in her third confinement, the aid of a doctor and was attended by a midwife. After the delivery she was seized with a hemorrhage which rapidly became formidable. Seeing her impotence to meet the emergency the midwife fainted, and during her syncope the woman succumbed.

ST. JOHN'S GUILD.—A "Lady Washington Reception" will be held at the Academy of Music on Tuesday, April 6, in aid of the building fund of the floating hospital which it is proposed to establish under the care of this society.

PRIZE ESSAYS to be presented to the Committee of the American Medical Association should be sent to Dr. L. P. Yandel, at Lonisville, Ky., as Dr. J. D. Jackson, Chairman of the Committee, is spending the winter in Florida, and it is feared that the state of his health will not permit him to return in season to attend to his duties.

DR. JÜNGKERS, Professor of Surgery in the University of Berlin, on the 17th of January completed the fiftieth anniversary of his appointment, and was presented by the Emperor with the Star of the Order of the Crown of the second class.

CHLOROFORM DEATH: RESCUCITATION BY NÉLATON'S METHOD.—Dr. Freuzal reports (*Progrès Médical*, January 30), a case in which a child, apparently dead from the effect of chloroform, was recalled to life by inversion and suspension by the feet, and forced movements of the chest. The face and lips were discolored, and there was neither heart-action nor respiration. The effect of inversion was very rapid, and markedly efficacious.

SCHOOL HYGIENE.—The physicians of Eastern Middlesex, Mass., have petitioned the Board of Health to enforce "such rules as will prevent the attendance in public schools of any child residing in a family where there is, or has been, a case of measles, scarlet fever, or whooping-cough, until the physician in attendance on such case of disease shall have furnished a certificate that in his opinion the period of danger from infection is past, and that he knows that the infected premises have been thoroughly disinfected."

"SALT LAKE CITY MEDICAL SOCIETY."—The regular practitioners of medicine in Salt Lake City organized a society on the 1st of February with the above title. A constitution and by-laws were adopted, together with the code of ethics of the American Medical Association, and the following officers were elected: *President*, W. F. Anderson; *Vice-President*, J. F. Hamilton; *Secretary*, U. C. Richards; and *Treasurer and Librarian*, J. M. Williamson.

DR. MEREDITH CLYMER.—The remarks upon Dr. Sayre's paper before the New York Society of Neurology and Electrology (vid. page 120), commencing "in view of the absence of those members," etc., should have been credited to Dr. Clymer.

ANTI-VACCINATION.—A number of the French Canadian physicians of Montreal have formed an "Anti-compulsory Vaccination League." They intend to oppose, by all legal means, the operation of the vaccination law, and to endeavor to procure its repeal.

A NEW MEDICAL COLLEGE IN MILWAUKEE is contemplated, and will be the first institution of the kind in Wisconsin. A number of enrolments for matriculation have already been made, and its formal opening is put down for the 15th of March.

NEW YORK STATE INEBRIATE ASYLUM.—Drs. John J. Orton, of Binghamton, and William C. Wey, of Elmira, and Benjamin F. Bruce, of Lenox, have been appointed by the Legislature to be managers of the N. Y. State Inebriate Asylum at Binghamton.

STUDENTS AT THE JEFFERSON MEDICAL COLLEGE.—The recently issued catalogue of the students at this school shows that four hundred and eighty-three were in attendance during the session of 1874—75, the class of the year before being smaller by ten students.

"SOUTHERN ILLINOIS MEDICAL ASSOCIATION" is the title of a new society recently organized at Jonesboro, and of which the following are the officers elect: *President*, Dr. H. C. Hacker; *Vice-Presidents*, Drs. McLain and Wardner; *Secretary*, Dr. G. W. Schushardt; *Treasurer*, Dr. W. C. Lence.

COLORADO boasts that one-half of its population consists of reconstructed invalids.

CO-EDUCATION OF THE SEXES IN THE MICHIGAN UNIVERSITY.—The experience of the past year strengthens the position of the women in this institution. The whole class numbered about three hundred and sixty, and of these about fifty were women. As regards preliminary education, the women have the advantage, many of them having previously been teachers, and most of them having arrived at maturity. They have so far carried off a large share of the honors, and it is admitted that they generally stand higher in their classes than the men. The average age of the women is thirty years, while that of the men is twenty-four and a half, the oldest man and woman being respectively forty-five and fifty, and the youngest eighteen and nineteen.

AN EPIDEMIC OF TRICHINOSIS has appeared in the neighborhood of Hanover. Some 400 persons have thus far been attacked, and of these 21 have died.—*Rundschau*, Dec. 1874.

ELECTRICITY A SUBSTITUTE FOR GAS.—A Russian claims to have discovered a process for producing light by electricity, which is thus described: A small tube of glass, not more than six inches in length, is filled with a pencil of charcoal, the air is exhausted, and the tube hermetically sealed. A moderate current of electricity is then passed through the charcoal from an ordinary electro-magnetic machine, causing it to glow with a very brilliant, but at the same time soft light. It is stated that the charcoal does not apparently suffer consumption, but lasts for an indefinite period, and that the strength of the current required is so small that two hundred of these lights, at a considerable distance apart can be easily maintained by a single machine. The inventor claims that he can light the whole city of St. Petersburg, both street-lamps, stores, and private residences, by a single fifteen horse-power machine, with no greater cost than that of running the machine.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, March 15.—Obstetrical Section of the Academy of Medicine; Medico-Chirurgical Society; N. Y. Society of Neurology and Electrology; Pathological Society of Brooklyn.

Tuesday, March 16.—N. Y. Obstetrical Society; N. Y. Dermatological Society; North-Western Medical and Surgical Society; Medical Society of the County of Kings, "School Hygiene in reference to the Physiological Relations of Age and Sex to Mental and Physical Education." Alexander Hutchings, M.D.; Newark Medical Association.

Thursday, March 18.—N. Y. Academy of Medicine, "Significance of Disturbed Action and Functional Murmurs of the Heart," by James R. Leaming, M.D.; Medical Association of the Eastern District of Brooklyn.

Friday, March 19.—Medical Library and Journal Association, "On the Elements of the Diagnosis in the different Stages of Disease of the Hip-joint." Dr. C. F. Taylor.

Medical Department of Life Insurance.

THE RELATION OF SYPHILIS TO HEALTH AND TO LIFE.

By R. W. TAYLOR, M.D..

SURGEON TO THE N. Y. DISPENSARY, DEPARTMENT OF VENEREAL AND SKIN DISEASES; PHYSICIAN TO CHARITY HOSPITAL.

MR. EDITOR:—If your subscribers are not already tired of the question of syphilis, in its bearings upon health and longevity, I should be pleased to contribute some additional thoughts on this to me most interesting topic. The questions as put by you to Dr. Sturgis (*MEDICAL RECORD* of last year) appear to me to cover the ground pretty completely. First, "What influence does syphilis have upon the duration of life as regards insurance?" Second, "Will a man, of the upper and middle classes, who has become syphilitic, reach the age to which he would have attained had he not been syphilitic?" Now, in order to answer these questions, I shall have to consider the nature and course of syphilis as a disease, and also to determine as nearly as possible the condition of the constitution of patients generally, and how they may be affected by it. First, let us determine, if we can, what syphilis is. In my discussion of this subject, you, of course, know that I can only give you, approximatively, statements which are based upon facts and observation; still they will, I think, be such that they will render you material service in the discharge of your duties. My consideration of syphilis will, you understand, be general in its character, and I shall not enter into a detailed description of its manifestations, as such a course would here be inappropriate and unnecessary. Let me remark that I shall not quote statistics, and I mention the fact now because it may be thought that they would throw light upon our inquiry. A careful review of such as are accessible has convinced me fully that we have none at present worthy of reliance, certainly none which will warrant the deduction of conclusions such as are needed at this time. I will here give you an illustration: Zeissl, in his text-book (*Lehrbuch der Syphilis*, 2d edition, vol. ii., page 83, Vienna, 1873) gives the percentage of deaths by syphilis as occurring in the General Hospital in Vienna. In 1862 the number of syphilitics treated there, male and female, was 1,097, of which eight died. The causes assigned were pulmonary tuberculosis, or nephritis albuminurica, and a woman is said to have died of perimetritis septica. Leaving out of consideration the fact that the further history of a large number of these patients was not known, it is readily seen that doubt might well be entertained whether those diseases causing death were really due to syphilis at all. In fact, many of the reports of chronic disease causing death, which we find in hospital statistics, are utterly unworthy of mention in this light, since the syphilis in many was so remote that its sequence was not accurately traced. Let us cite an instance: A patient, who in his early days was syphilitic, years after dies of, we will say, amyloid degeneration of some of the viscera. Very many, without further inquiry, would establish the etiological chain with syphilis as the cause. I think that there are very many, even intelligent men, who thus argue in a given case in which syphilis occurred in early life, and in which a chronic disease was observed later on, that syphilis is the sole

cause, and they rest their inquiry after the fact of early infection is proved. Thus it is that many cases of death are attributed remotely to syphilis, whereas it was perhaps really not the cause, or again, but one of a number of causes. And further, there are undoubtedly many cases in which syphilis was the cause of death, and in which that fact escaped. You can see at the outset how difficult it is to establish, in an accurate manner, the relation of an early attack of syphilis to affections observed years after. Now then, as I have discarded published statistics, I am left to draw my conclusions from actual observation, and I think this is the true source, and the one which will yield the most satisfactory conclusions. Those persons who treat syphilitics year after year in private practice have opportunities for the observation of the course of the disease such as cannot be obtained in any institution. Such cases are peculiarly appropriate for our present consideration, as they consist really of such persons who apply to you for insurance upon their lives. I think that if we study, for instance, the course of the disease in from fifty to one hundred private patients, we can form better ideas of its fatality than we can by the examination of statistics. These patients are in varying circumstances and conditions as to constitution, habits, social status, trade surroundings, etc., and from the continuous study of their medical history the picture of syphilis in all its phases may be seen. This, indeed, is the only true way to determine the course of that disease, and such a line of study is the only one which will put the observer in the position to answer your questions accurately. A man's syphilitic history does not end with the healing of his chancre, and with the disappearance of the secondary lesions. It is necessary to observe the future of such a man, to consider how he is influenced by intercurrent diseases, or how they are modified by his syphilitic constitution, how his health is affected, and what is the condition of his offspring if he has such. It may be said truly, that if a man is once syphilitic his future life is a medical problem. Such cases are of much interest to me, and I endeavor always to trace the bearing of the disease upon their future career. I think that I need not say more to prove that the position which I have taken as regards the solution of this question is the true one, and the one most appropriate for my present purposes. Fortunately, particularly for Americans and the majority of Europeans, the syphilis of to-day is comparatively a mild disease. It is unnecessary to go into the study of the probable causes of this mildness in the course of syphilis, but certainly the fact is well established, and it may also, I think, be added, that it becomes markedly milder as years go on, owing no doubt to our more intelligent methods of cure, and perhaps to the advances of civilization. Thus we are ceasing to see such frequent instances of vast ulcerations as were seen say fifty years ago. This fact is also noticed in France, and is well shown by the reply of a physician to another, who wrote to him asking how often he found tertiary lesions.* The reply was, that the treatment to which he submitted his patients was such as did not allow tertiary accidents to follow. Indeed, I think the extreme dread which the community once entertained regarding syphilis is growing markedly less, owing to the fact that so many cases occur in which the disease runs a favorable course. Then again, I think that the great progress which has of late been made both in therapeutics, pathology and diagnosis of the disease are being very

* *Recherches Statistiques sur l'étiologie de la syphilis tertiaire*. By L. Jullien, page 7, 1874.

widely appreciated by the profession, much more so than formerly, and that they treat the disease more in accordance with science than in past years. Thus, then, we are not called upon to consider the influence of a terrible and fatal scourge, but, on the contrary, of a disease which is in the vast majority of cases amenable to proper treatment, and which may be so arrested in the individual that the health of future generations will not be impaired by it. Indeed, in the treatment of this disease, which is so widespread in its occurrence, such progress has of late been made that medical men may with pride claim that, if this portion of their study is not an exact science, they have at least reduced its art almost to a state of certainty. We are ceasing to read such diatribes as our forefathers read upon disastrous effects of mercury, and anti-mercurialists are greatly outnumbered by those who now know what benefit that mineral will produce, while they know how to avoid its toxic effects. Indeed, I think that, if reliable statistics could be obtained, it would be shown that the late lesions of syphilis are not by far as often of occurrence as they formerly were, and that there is a decidedly smaller number of cases of infantile syphilis. Of this department of medicine we may certainly be reasonably proud, certainly in no other has more real and substantial progress been made. In this connection it is well to remember that besides our more enlightened skill we now have as aids to us in treatment that very valuable drug, the iodide of potassium. It might be thought that the luxuries and indulgences of a rapidly increasing civilization might have a harmful influence upon the course of syphilis; but I think that this objection is not real, since, with our heightened civilization, we have a corresponding increase and knowledge and attention to hygiene. All these conditions, then, of national prosperity and personal enlightenment, constituting as they do our civilization, have an indirect, but, I think, potent influence upon the course of syphilis. Certainly it may be reasonably hoped that the severity of syphilis will gradually become even less than it is now. These considerations, you see, are pertinent to my subject, and are necessary to the proper unfolding of my views.

Having now established the general character of syphilis as a disease affecting the nation, let us consider what it is essentially. Let us study in what way it affects the economy, and in what manner it may lead to death in persons in general. After that we shall be prepared to apply the facts thus obtained to the various classes of men which constitute society, and from which individuals come with whom you may enter into relations in which the condition of their health is the cardinal point.

Without considering the contagious character of syphilis, it may be in general stated to be a constitutional disease in which there are tendencies to local hyperæmia, which are generally most active and almost confined in their occurrence to its early stages. Besides this general morbid tendency it produces cell changes, and gives rise to new formations in various organs and tissues. Thus, then, in its early stages particularly it may induce local congestions which may even compromise life, this event depending upon the severity of the process, as well as upon the particular part involved. Thus, while in the pharynx an hyperæmia may be only an annoyance, in the brain it might be the cause of death. The tendency of the disease to thus, as it were, put out of balance the controlling action of the blood-vessels, is quite well limited to its early stages, and gradually becomes less marked as the disease grows old. But

the greatest danger of syphilis in destroying life is in its power of producing new growths, and this tendency, unfortunately, is of quite long duration, and it manifests various phases of severity. Fortunately for the human race, the integument which, as is well known, may be largely diseased without endangering life is the tissue which is most frequently involved by syphilitic neoplasms. Thus it is that so few die because of it. Yet it must be stated, however, that all organs and tissues may be affected, particularly those in which there is much connective tissue and which are abundantly supplied with blood-vessels and lymphatics. No organ possesses an immunity from the development of syphilitic new growths, or, as we call them, gummy masses, and when these latter affect the integrity of organs essential to life, it is compromised more or less. This general sketch, however, does not fully explain the essential nature of syphilis. There is also an altered condition of the blood, in which chemistry has demonstrated certain changes in its composition, and the microscope has revealed that certain peculiar little bodies are contained in it. We are unable to go further than this, and although we know from the observation of facts that it possesses contagious properties, we cannot determine in what this quality resides or of what it consists. This is one of those so intimately associated with life that we are unable to fathom it. Syphilis, then, is to be most feared in consequence of its power of producing local congestions and infiltrations of morbid tissues into organs essential to the maintenance of life. The condition of the blood which I have indicated also becomes, in some rare instances, a cause of general mal-nutrition which may eventuate in death. The state of the system thus induced we call syphilitic cachexia, and in some instances it is a formidable one. I shall revert to its consideration further on. Now, then, I shall endeavor to show how the various organs may be so affected by syphilis that death may be the result. In this I wish to be understood as saying that death may be caused, not of necessity is caused. Naturally we begin with the brain; very slight lesions of it often induce death.

SYPHILITIC LESIONS AND AFFECTIONS OF THE BRAIN WHICH MAY CAUSE DEATH.

Inflammation of the *pia mater* and arachnoid, consisting in hyperæmia and thickening in various degrees, and involving more or less surface.

Inflammation of the *dura mater*, with or without gummy deposit.

Internal cranial periostitis, either simple or gummy.

Gummy tumors in the cerebral hemispheres.

Acute inflammation of the arteries and capillaries.

Chronic inflammation of the same.

Thrombosis by fibrous coagula.

The spinal cord may also be similarly affected, so that I need not enter into detail, except to mention that syphilitic disease of the vertebrae may involve the cord and cause death.

The upper parts of the air-passages may also be affected by syphilis, and death has been known to follow obliteration of a bronchus by syphilitic inflammation and new growth.

Though our knowledge of the effects of syphilis upon the lungs is not as precise as we should wish it to be, yet do we know that these organs, so vital to existence, are, we may say, somewhat frequently attacked by syphilis. I shall, further on, devote considerable time to the relation of syphilis to pulmonary troubles, as these are of vast importance in medicine.

We are warranted in naming the following lesions as being produced or induced by syphilis:

Interstitial proliferation of connective tissue, with concomitant processes and subsequent results.

Gummous infiltration, more or less local or diffused.

Degeneration of arteries, either acute or chronic, giving rise to hæmoptysis.

The kidneys are said to be sometimes affected by syphilis, though of course it is difficult to trace the connection between the lesion and the disease. The lesions are not well understood. The structure of these organs is such as would seem to render them especially liable to the specific action of syphilis. Upon this subject Rayer, in his classical work, "*Traité des Maladies des Reins*, Paris, 1840,) says: "It is not easy to well appreciate the influence which constitutional syphilis may exercise upon the development of albuminous nephritis, for it is very rare to see this disease in syphilitic persons who have not been subject to other causes, of which the influence in producing affections of the kidneys could not be contested. However, I have seen cases in which the influence of the constitutional affection has appeared to me so striking that I have not hesitated to attribute at least, in a great part, the development of the affection to the syphilitic cachexia." Coming from a man who was well versed in questions of syphilography, this statement is very important. We may have, then, as induced by syphilis in the kidneys:

Hyperæmia, which may lead to structural change.

Interstitial nephritis.

Gummous infiltration.

Degeneration of vessels and of capillaries.

The liver may be so seriously affected by syphilis that its function is destroyed. It also is liable to the same forms of lesions as are the kidneys. A case is reported in which death was caused by occlusion of the portal vein by gummy deposit or tumor. So little is known of the pathology of the spleen that I cannot advance anything regarding its disease and the effects on health. It is to be presumed, however, from analogy, that even extensive degeneration of it would not cause death.

In some rare cases syphilis affects the œsophagus to such an extent that a fatal issue results. Cases of the occlusion of the calibre of this tube causing death are on record. Follin (*Traité de Pathologie externe*, Paris, 1872) reports a case which was due to syphilis, cured without local treatment by internal medications; while West (*Dublin Quarterly Journal*, 1860) records a fatal case. These facts go to show that this affection must be regarded as one of the probably fatal accidents of syphilis.

I am unable to consider the action of syphilis upon the small intestines, as they are so seldom if ever attacked, and the diagnosis of such an affection would be attended with much uncertainty. The rectum, however, may be involved by syphilis, and a condition may result therefrom which may finally lead to death.

(To be continued.)

THE influence of age upon suicide has been lately examined by Dr. O'Dea, and it appears that the *maximum* of suicides of both sexes occurs between the ages of 25 and 55. Previously to the 25th year there is a sudden increase from two suicides between the ages of five and ten, to 136 between 20 and 25. After 55 the tendency to suicide declines, but more gradually than it rose, except at 65, where the number increases from 81 to 83—a rise so slight, however, as to be little worth considering.—*Insurance Times*.

ON THE MORTALITY AMONG RHEUMATIC RISKS.*

By A. HUNTINGTON, M.D.,

OF NEW YORK.

GENTLEMEN—In the last annual report of the Medical Director allusion was made to the subject of rheumatism, and some few general observations regarding it were made at that time, with promise of a fuller and more complete inquiry at some future period.

During the past year the subject has been taken up, and as careful an investigation made as it was possible to make with the dates and information at our command.

The result of this investigation is given below, and while it does not establish grounds upon which the Medical Examiner feels he can stand and act *positively* in regard to the acceptance or rejection of rheumatic risks, yet it confirms, as far as it goes, the impressions of medical men in relation to the effect of rheumatism, and will serve to make the Medical Examiners of this Company at least extremely careful in the selection of risks which have any history of rheumatism.

It is to be regretted that the applications heretofore used (and in this respect all companies were alike) were such that the particulars necessary to a *full* understanding of rheumatic attacks in applicants could be obtained in but comparatively few cases, and it is owing to this that we are unable to show, as we wished to do, the effect of rheumatism at the different periods of life, because the dates at which the individuals suffered the attacks are rarely mentioned, nor is even the character of the disease specified in the great majority of instances; still, with all this against us, we have been enabled to present some facts which are, to say the least, suggestive. We are glad to say that in the new application recently adopted by the Chamber of Life Insurance these defects of the old forms are remedied, and hereafter we shall be able to command far greater accuracy of detail.

Our investigations have been made on 844 cases, who report in their applications that they have suffered from rheumatism at some time in their past lives. This includes all grades of rheumatism, from "slight muscular" up to "acute inflammatory." Many of these cases have, of course, lapsed; so that, as a whole, we can follow the 844 but a little way from the threshold; and owing to this fact our observation has extended to but $7\frac{1}{2}$ years' average to each individual. Therefore, we can only say of them, as a whole, that they came from all classes of the people—were engaged in the various pursuits of life—and were of all ages upon which policies are usually written.

Of these 844 we have the height and weight in 674 instances, but in the remaining 170 these records are wanting. It is scarcely probable, however, that these 170 would disturb the averages to any great extent.

We find that the average weight does not vary *materially* from the standard, yet is, in the main, *somewhat above* it.

Having stated the above, we find little else to attract our attention till we come to the deaths among these rheumatic cases; and these we find were 114 in number, *i. e.*, there were 114 of which we are cognizant. Of those who died having allowed their policies to lapse, or of the cause or manner of their deaths, of course we cannot speak; but it is just to presume that a fair proportion of these died from the causes which we shall hereafter show to have been so fruitful among the 114

* Annual report to the directors of a life insurance company in this city.

of which we are speaking. These 114 deaths were from all causes.

Table of height and weight in the 674 cases:

Height.....	5 ft.	5.1	5.2	5.3	5.4	5.5	5.6	5.7	5.8	5.9	5.10	5.11	6 ft.	6.1	6.2	6.3
Number.....	10	2	4	14	24	33	65	103	141	84	92	59	30	9	3	1
Av. Weight...	128½	141½	131	126	142	138	142½	148	152	163	164	164	173	186	208	235
Am. Standard.	115	120	125	130	135	140	143	145	148	155	160	165	170	175	185	195

The heights and weights of these are given in the following table, and do not differ materially from the table of the 674 cases above. In 15 of these cases the weights and measurements are missing; we have therefore made our table upon the 99 remaining.

Height.....	5 ft.	5.1	5.2	5.3	5.4	5.5	5.6	5.7	5.8	5.9	5.10	5.11	6 ft.	6.1
Number.....	2	2	4	6	9	18	14	18	15	8	2	1
Av. Weight...	115	132	135	142	145	157	155	165	162	161	159	230
Am. Standard..	115	120	125	130	135	140	143	145	148	155	160	165	170	175

The average age, at death, of the 114 was 46 years and 9 months, distributed among the ages as follows:

Ages.	25 to 35	35 to 45	45 to 55	55 to 65	65 to 75	
No.	20	26	40	22	6	114

As we have said, these 114 deaths were from all causes, but when we examine more critically into these causes of death among individuals who have had rheumatism, and compare them with the same causes among others who have not had rheumatism, we find that death arising from diseases of certain organs occurs far more frequently among those *having* than among those *not having* rheumatism.

This is in accordance with the generally received opinions among medical men, viz., that rheumatism, and especially certain varieties of it, is quite likely to be followed by disease of certain organs, more particularly the heart, which, in many instances, eventuates in brain or dropsical difficulty.

We shall use, therefore, only three of the causes of death in making our comparison, for the reason that, while many and various diseases come in for notice, these three, viz., heart disease, brain disease and dropsy, figure so conspicuously as to make it evident that they are the ones upon which the comparison should be instituted.

This comparison is based upon 1,000 deaths, 114 of which furnish a history of rheumatism; and 886 are without any such history, so far as we can learn.

Among the 144 deaths, of persons who during life had suffered from rheumatism; 21, or 18.42 per cent., were from heart disease; 22, or 19.29 per cent., were from brain disease; and 4, or 3.5 per cent., were from dropsy. Among the deaths of the 886 who had not had rheumatism there were 35, or nearly 4 per cent., from heart disease; 101, or 11.39 per cent., from brain disease; and 16, or 1.8 per cent., from dropsy. Placing these figures side by side in the form of a table, we have the following:

	Heart Disease, Per cent.	Brain Disease, Per cent.	Dropsy, Per cent.
With rheumatism (114 cases).....	21	22	4
Without rheumatism (886 cases).....	35	101	16
Total.....	56	123	20

Of the above it is but reasonable to suppose that some of the deaths attributed to brain disease and dropsy should, by *right*, have been included among

diseases of heart; and it is by no means improbable that some of those dying of heart disease or brain trouble, who come under the head of *non-rheumatics*, *ought* properly to have been in the other group.

Thus we see that those individuals who are afflicted

with rheumatism contribute to deaths from heart disease about 4½, where those without it contribute but 1; brain disease, 1½ to 1; dropsy, 1½ to 1.

"Rheumatism" is a thing so common that, were we arbitrarily to exclude all who say they have had rheumatism, we should almost be unable to do business. Nor is this necessary, for it is only certain kinds of rheumatism that we believe so apt to be followed by heart trouble; and we now hope, through the form of the new application, to get such particulars of information as will enable us to decide intelligently when to admit and when to exclude rheumatic applicants.

The plan pursued in this investigation was as follows:

The risks were divided into four different classes, according to the several grades of rheumatism, as nearly as could be determined by the statements of the applicants, and the tabulated statement below, prepared by the Actuary of the Company, will show all the points of interest, and is self-explanatory.

	Lives.	Exposure.	Expected Mortality.	Actual Mortal.	Ratio.	Duration of Pals.
Rheumatism...	294	2160½	30.57	54	1.766	7.35
Do, slight, occasional.....	396	2143½	29.35	31	1.056	7.00
Do, acute, fever, or, inflammatory.....	164	681½	8.98	11	1.225	6.55
Do, in limbs.....	140	1073¾	14.68	18	1.266	7.66
	844	6058¾	33.58	114	1.364	7.18

I will only add that, in consequence of the vague manner in which many applicants speak of their rheumatism, and the general temptation to conceal the severer forms, or make them appear as insignificant as possible, it is very reasonable to believe that the above ratios do not express the actual facts, but that many of the cases which were designated as "rheumatism" simply, or "rheumatism of limbs," or "slight rheumatism," *ought* to have been classed among the "acute inflammatory" cases.

We give it, however, as it is, believing that we have at least an approximation to the facts, and that hereafter, when we shall be able to get the details in rheumatic cases more fully, we can make a much more exhaustive statement.

ACCORDING to the investigations of Mr. Ansell, of England, the mortality, from age 15 to age 35, among the children of physicians is less than among the children of the same ages of either the clergy or the legal profession.

AUTOPSY OF THE TRING CENTENARIAN, WHO HAD ATTAINED THE AGE OF ONE HUNDRED AND ELEVEN YEARS.*

By SIR G. DUNCAN GIBB, M.D., LL.D.,
PHYSICIAN TO THE WESTMINSTER HOSPITAL.

AN account of the autopsy of the old dame, Mrs. Elizabeth Leatherlund, known as the Tring or Hertfordshire centenarian, just deceased, who was within three months of attaining the great age of one hundred and twelve years, will be most fittingly recorded in the pages of *The Lancet*. Of the correctness of her age, as I have already had occasion to state in a communication brought before the British Association at Belfast, in August of last year, there is no doubt, and very shortly a paper of mine, embodying all the proofs of this, will be brought before one of our scientific institutions. But it may be stated here, that she mentioned she was born at Chinnor, in Oxfordshire; she gave the Christian name of her father correctly, as well as her own; her maiden name she described as Hferne, although spelt Horam in the Parish Register of baptisms at Chinnor for 1763, in which occurs this:—"Elizabeth, daughter of Thomas Horam, Travailer, April 24." No subsequent entry occurs in this register for thirty-seven years, giving her own or father's name, which disposes of an objection to her age that was brought forward in *The Times* some months back. Then she stated she was twenty-eight years old, or probably twenty-nine, when her first child was born. When I saw her in October, 1873, I felt that the crucial point would be the discovery of the date at which her eldest son and child, Samuel Leatherlund, with his wife and children, and other persons to the number of thirty-five, were drowned by the upsetting of a large wagon laden with hop-pickers, on crossing a wooden bridge over the river Medway, at Hadlow, in Kent, many years back. She could not give me the year, but on writing to Dr. Miles Coverdale Hooker, at Hadlow, he at once kindly furnished me with the date of the catastrophe, as October 20th, 1853, and sent me a photograph of the monument, with the names of Samuel Leatherlund, his wife, children, and kinsfolk, with their ages, who were buried there. Samuel's age was down as fifty-nine, and, curiously enough, all this information must have been correctly furnished by one daughter who escaped, as I learnt by referring to the newspapers of the time, which gave a very full account of the affair, together with the various inquests on the bodies. If the son was fifty-nine, or probably near upon sixty when he lost his life in 1853, he would have been eighty-two now, and deducting that from one hundred and eleven or one hundred and twelve, the age she would have shortly reached, it would have made twenty-nine when she was confined with him, which tallies with her statement. This, medically, is a matter so clear that it requires no further comment. By her husband, Joseph Leatherlund, a private in the Bucks militia, who died at Carrick-on-Shannon about 1816, she had three sons and two daughters. The eldest was Samuel, and the youngest and only surviving is Saborah, who says she is near upon seventy (although she looks younger), and the mother of nine children, the eldest of whom is thirty-seven and the youngest sixteen.

On my visit to the old dame, in October, 1873, a most careful physical examination was made, including the use of the laryngoscope, which at first very

much frightened her. Generally speaking there was an absence of senile changes in any part of the body, and I compared her condition at the time in some respects to that of a girl of sixteen. She made the tenth living centenarian I had examined, and unquestionably she looked ten years older than any of the others. My friend Mr. R. N. Lipscomb, of Tring, who had occasionally seen her, kindly promised to let me know when anything happened to her.

On January 19th a letter from him, late in the day, informed me of her death the preceding night. Accordingly, I proceeded early next morning to Tring, to meet him, for the purpose of examining her. He was unfortunately called away to a distance, but he left instructions with his assistant to aid me in his absence, and we proceeded together to the Red Lion Inn, Frogmore street, where I made the autopsy myself, the assistant recording the appearances as they were described to him.

Autopsy at 12.30, about thirty-six hours after death.—Height during life was four feet nine or ten inches; the body, therefore, was small and proportionate to her height. The rigor mortis was slight, and no odor was exhaled from the body. The integuments generally were of a yellow color with a shade of brown, but not darker than they appeared during life. They were a little loose over certain parts of the body, but the attenuation of the muscles, especially about the neck, did not seem to be so great as when she was seen by me in October, 1873. The muscular development generally was fairly good, and no decided emaciation to speak of existed. The mammae were firm and well developed, though small, with no dark areolae around the nipples. Over the abdomen were the usual marks seen in persons who have borne children. In sewing up the body afterwards, the skin was so tough that the needle would scarcely penetrate it. On reflecting the integuments over the chest and abdomen, a little adipose tissue was found over the pectoral muscles, and over the abdominal muscles it varied in thickness from an eighth to nearly a quarter of an inch. The cartilages of the ribs at their junction with the bone were cut through with the greatest ease and facility, the knife meeting with no resistance from any osseous changes. The cut surface presented a narrow rim of true white cartilage, whilst the other part possessed a brownish tinge, the result of some change allied to fatty degeneracy, for a slight roughness was manifest to the finger, although the middle structure was quite soft; but before division of the costal cartilages, the thorax could be compressed with ease, through their elasticity, as I had seen during life.

The lungs were healthy, crepitant throughout, and had the usual appearance. Some slight congestion of the posterior part of the left was present, which, to some extent, may have been hypostatic, yet, associated with what was described as a trifling cold, it was the immediate cause of death. At the apex of each lung was a trifling adhesion, readily broken down, the connecting membrane having the appearance of ordinary areolar tissue. Both lungs at the margins of their lower lobes had an emphysematous fringe. The heart was perhaps a little large in proportion to the size of the body; it weighed, with the arch of the aorta, thirteen ounces exactly. In structure it was soft, a little flabby, and had a slight covering of fat. The coronary arteries were distinctly observed, but had not undergone any change. The right side of the organ was filled with dark clots of blood, whilst the left was empty. The muscular structure, cavities and valves appeared to be normal. The arch of the aorta generally was enlarged, dilated and somewhat attenuated;

* From *The Lancet* of Jan. 30, 1875.

at its commencement the circumference was four inches and one-sixteenth, whilst at its termination it was three inches and one-fourth. An atheromatous patch, the size of a silver threepence, was present on the lower surface of the transverse portion of the arch, whilst at the commencement of the anterior and left part of the ascending portion a ridge of atheroma existed, which did not involve the semilunar valves.

On opening the abdomen scarcely any trace of the omentum was observed. The stomach and alimentary canal were perfectly healthy, and not distended with flatus. The liver was of fair average size for the body, of firm healthy structure, possessing a light claret-brown color, and free from any white spot or patches. The gall-bladder was large in proportion to the liver, and filled but not gorged with bile; it contained no biliary calculus. The spleen was of the usual purple color, comparatively small, slightly curved in shape, but healthy and firm. Both kidneys appeared to be healthy, the cortical and medullary portions fairly distinct, but in general structure soft and flabby. The ureters were normal, and so was the bladder, which was nearly full of urine. The uterus was very small, the Fallopian tubes and ovaries equally so, all quite healthy. The thoracic and abdominal aorta and other blood-vessels were soft, and free from any abnormal changes. The tongue, larynx and trachea were removed for examination. Some of the papillæ on the dorsum of the tongue were much enlarged. The larynx was small and compact; the epiglottis, which had a slight notch on its superior margin, possessed the natural color, shape and appearance of early life. The vocal cords, short in length, had the merest tinge of yellow, but were otherwise normal. The aryteno-epiglottidean folds, the ventricles and all other parts of the larynx were as perfect in their formation as in a young person. All the cartilages of the larynx were flexible, with an absence of any calcareous changes, unless in the central solid parts of the wings of the thyroid. The rings of the trachea were white and glistening, perfectly flexible and soft, and could be compressed in any direction. The os hyoides was thin, the great cornua slender, one of them fractured on removal, and the right lesser cornua elongated.

The heart, tongue, larynx and trachea were brought away, and have since been presented to the College of Surgeons for their museum.

I must not forget to mention that the cornea of both eyes was free from any arcus senilis or annulus, although her sight had not been very good of late years. Yet she had been able to knit twine bags almost to the very last. She was of pure gipsy descent, and her father's family of Herne or Horam was, it appears, well known in Herts, Bucks and Oxon, as belonging to wandering tribes of gipsies.

THE COMPARATIVE MORTALITY OF LARGE TOWNS.*

BY BALTHAZAR FOSTER, M.D.

As the time at my disposal is short, I have drawn up in a tabular form the statistics on which my remarks are based. The table gives the rate of mortality from all causes, and certain special causes, for twenty years (1851 to 1870), in Birmingham and six other large towns, as compared with the rate of mortality in the country generally (England and Wales), and in twelve healthy rural districts. The registration districts, I should observe, do not correspond with the boroughs in the cases of the six provincial towns. In each in-

stance the registration district is limited to the worst part of the town, and so the comparison is a fair one, except in the case of Bristol. The registration district of Bristol includes not more than one-third of the city, and that the most unhealthy part; the death-rate, consequently, appears much higher than that of the whole city. In the case of London, on the other hand, the area of the registration district is so wide that the death-rate is lowered by including the suburban districts with the central portions of the city in a common average. A glance at the second column of the table shows that the death-rate of the Birmingham district, from all causes, places our town higher in the health scale than Liverpool, Manchester, Leeds, and Sheffield (I omit Bristol for reasons above stated); while our death-rate is greater than that of London, and exceeds that of the whole country by about 4 per 1,000. The towns lower in the health scale exceed that of the whole country as follows for the twenty years:

Sheffield.....	6.5 per 1,000
Leeds	6.5 " "
Manchester.....	nearly 10. " "
Liverpool.....	13.7 " "

The reduction of this excess is the work before the sanitary authorities in these districts. Passing on now to the next column, which shows the fever death-rate, Birmingham stands exceedingly well, being, with London, for the twenty years' average, the healthiest of the six great towns, and for the last decade having a lower fever death-rate than the average of the whole country. Liverpool, which is by far the worst of the great towns in its fever death-rate, has a population which suffers from true typhus, a form of fever exceedingly rare in Birmingham. After this column, however, the superiority of Birmingham ceases, and we come to the two great blots in its sanitary records. The diarrhoea and cholera death-rate in the next column shows that the Birmingham diarrhoea death-rate is twice as bad as the average of the whole country, much worse than that of London and Bristol, about equal to that of Sheffield and Leeds, and is only exceeded by the death-rate in Manchester and Liverpool. If we take, however, the proportion of deaths from this class of disease, and the deaths from all other causes during the twenty years, as stated in column nine, Birmingham stands second in this black list, being only surpassed by Liverpool—the most unhealthy of our great towns.

Moreover, when we bear in mind that during these twenty years Liverpool has suffered from several cholera epidemics, while Birmingham has enjoyed a wonderful immunity from this terrible pest, we cannot, I am afraid, truly say that Birmingham is much healthier than even Liverpool in respect to the mortality from diarrhoea. It is true the town has improved a little during the last ten years, but not sufficiently to justify any complacent indifference to the deplorably high death-rate from this cause. The next column refers to diphtheria. Here again, the results are startling. Birmingham is the worst great town in England as regards diphtheria, and this unenviable character has been acquired during the last ten years, the death-rate from this disease having gone up from .07 to .34 per 1,000 in the ten years; or, to state it more plainly, nearly five times as many deaths have occurred from diphtheria during the latter decade as in the former. A difference in registration will not account for this, as such a cause would have operated equally in other towns, and, moreover, the throat disorders which are confounded with diphtheria are not (with

* From the Medical Press and Circular of Jan. 27, 1875.

the exception of scarlatinal sore-throat) commonly fatal, and would not therefore affect the death-rate.

As regards this disease, Birmingham stands not only as the worst of the great towns without exception, but has a mortality nearly double that of most of them. Taking a momentary glance at two other columns in the table, a total zymotic death-rate and the proportion of deaths from zymotic diseases to deaths from all causes, we see that Birmingham is a little better this decade than for that ending in 1860. Comparing Birmingham with other towns for the first ten years of my table (the figures for the other towns for 1861 to 1870 not yet having been published by the Registrar-General), Birmingham was the worst town of all, except Liverpool and Sheffield, as regards the proportion of zymotic deaths to deaths from all causes. I specially refer to this, because these diseases are what we call, and call properly, "preventable diseases"—diseases which depend for their propagation on neglect of sanitary laws—diseases which admit of being partially, some would even say, very largely, stamped out. The simple statement that the death-rate in Birmingham, from preventable disease has been for twenty years past about 7 per 1,000, or that more than one-fourth of the total deaths has been from this cause, hardly conveys the magnitude of the evil. Every year there are now some 2,000 deaths from this class of preventable disease, and during the twenty years considerably over 30,000 persons have died in Birmingham from a class of disorders largely reducible by strict sanitary measures. During the year which has just closed the death-rate of the borough has gone up to the very high rate for Birmingham of 29 per 1,000, after having stood for the three years 1871, 1872 and 1873 at an average of 24.3 per 1,000.

The increase has been caused by the prevalence of certain zymotic diseases, especially small-pox. From this cause alone, during this one year, 637 persons have died; a number greater than the total deaths which occurred from small-pox during the ten years, 1861 to 1870. The remainder of the table I will not enter on, but would briefly refer to those two great sanitary defects which I have pointed out, viz.: the diarrhoea and diphtheria death-rates. Both of these classes of disease are eminently preventable. Diphtheria, when it was first studied in France, was referred to the poisonous effluvia from decomposing sewage. This view has again, of late, been greatly strengthened, and there is a strong opinion in the medical profession that diphtheria is especially a disease which is very closely connected with defective drainage. It often prevails epidemically in rural districts, in localities where such conditions exist, and is rather a disease of the country than of the town. In Birmingham, however, it has apparently taken up permanent quarters, and must consequently have found some local conditions especially favorable to its development and propagation. To these I will refer a little later on. In diarrhoea we have a still older enemy, one that has always prevailed in the town. The medical officer of the Privy Council, in his report for 1858, specially investigated the causes of the prevalence of diarrhoea in Birmingham and other towns, and he summed up his report with these words: "The excess of mortality has, in all the places, been coincident with one or other of two definite local circumstances—the tainting of the atmosphere with the products of organic decomposition, especially of human excrement, and the habitual drinking of impure water." Sewage, polluted earth, tainted air, and impure water, are the great factors of diarrhoeal disease; and there is reason to believe that diphtheria depends on somewhat similar unsanitary conditions. The

question now naturally arises: Are there special conditions in Birmingham favorable to the development of these diseases, and if so, what are they? We have not far to go for an answer. In this town, in 1870, the end of the period covered by my figures, there were 70,000 houses connected with privies and middens in the town. These houses contained a population of 325,000. In the words of the report of the Sewage Committee:

"The middens cover an area of thirteen and a half acres, and practically all of them, containing faecal matter and solid and liquid refuse, are open to the air. Some of them are situated beneath houses or workshops, and large numbers are built against the walls of houses, which are thus permeated with the filthy liquid soaking through the walls. The consequence is that the sewers are constantly fouled by the drainage from the middens, and that the surface wells generally become the receptacles of sewage matter, with which the earth surrounding the middens is absolutely saturated."

Registration District.	Death-rate from all Causes.	Fever ("typhus" of Registrar-General).	Diarrhoea and Cholera.	Diphtheria.	Scarlatina.	Total Zymotic death-rate.	Proportion of deaths from each cause to deaths from all causes.	
							Zymotic per cent.	Diarrhoea per cent.
12 healthy rural districts	17.1	.6	.4	.18	.53	2.9	17.	2.3

Manchester	26.6	.95	1.3	.07	1.14	8.	26.5	4.8
Leeds	26.9	.93	1.2	.18	1.27	6.8	24.5	4.8
Sheffield	33.3	1.35	2.9	.05	1.5	7.9	27.8	7.2
Birmingham (Parish)	33.6	3.1	2.9	.17	1.47	7.15	27.	8.3
	31.5	1.25	2.6	.04	1.56	6.98	26.3	7.5
	27.7	1.1	2.25	.05	.97			
	29.8	1.4	2.37	.13	1.26			
	28.4	1.3	2.2	.2	1.24			
	29.	1.4	2.1	.19	1.42			
	26.5	1.	2.2	.07	1.06			
	26.6	.79	2.	.34	1.32			

The foregoing is the table of mortality per 1,000 in-

habitants, from all causes and certain special causes, in Birmingham and eight other districts, during twenty years; the first line of each bracket referring to the period from 1851 to 1860, and the second from 1861 to 1870.

By our own words are we judged. The water of these surface wells, polluted with sewage, as our medical officer of health has frequently shown, is at present used by at least one-third of our population. Some 140,000 people in this town drink this death-giving fluid, and especially the children under five years of age, on whom the mortality from diarrhœa and diphtheria falls most heavily. The remedies for this state of things are obvious; they are two: (1) The abolition of the midden system, and the substitution of a system of weekly removal of refuse of all kinds from every house. This is the system which has been for years in operation in some of our healthiest towns. I am glad to say the corporation are vigorously endeavoring to carry it out here. The next remedy (2) is the abolition of all surface wells, and the substitution of a constant supply of the purest water we can get. If, by any means, a stream of pure water is poured into our courts and yards, in place of the tainted well-water which is now used, our health conditions in Birmingham will be greatly improved, and our mortality from preventable diseases largely diminished. This work, which you, sir, have proposed during your tenure of office, is our most urgent sanitary reform, and will, when accomplished, give a special honor to your mayoralty.

Miscellaneous.

INFLUENCE OF FACTORY WORK UPON THE HEALTH.—Dr. Hirt, district physician, delivered a lecture before the Breslau *Gewerbeverein* on the question: "Of what points regarding the employment of women and children in factories should legislation especially take cognizance?" It was stated that the German kingdom was the only civilized nation without factory laws, but the opinion was expressed that the time was not far distant when such legislation would also exist in Germany. Two events were mentioned which indicate the importance which the public attaches to this question. At the forty-seventh congress of the German naturalists and physicians in the section for Public Hygiene, this topic, next to the cholera, was regarded as of greater moment than any other subject discussed. Moreover, the Minister of Commerce has recently united with the Minister of Public Instruction in sending to the governments and physicians a programme in which they are called upon to institute certain very radical reforms throughout the German empire, concerning the condition of the female and youthful operatives in factories. This implies that factory laws are already under consideration. The enactment of such laws would naturally involve the imposing of further burdens upon the employers; but experience has taught that the protection of women and children in factories, by legislative enactments, is an absolute necessity. But if by reason of her feebler constitution the healthy woman needs greater protection than the man, then this must be still more true of sick women, women in the state of pregnancy, or those in child-birth, not merely for their own sakes, but also on account of their off-

spring. By statistics the speaker showed how dangerous and prejudicial to the pregnant woman is the employment in factories where the atmosphere is filled with particles of lead. That children, with their feeble undeveloped constitutions, stand in need of protection from the state, will hardly be questioned by any one. The first question which arises is, at what age ought children to be allowed to work in factories? In England, at present, this age is fixed at the tenth year, and according to our regulations children under twelve are not permitted to become regularly employed, and from twelve to fourteen years of age they can be employed in the factories only six hours, while from fourteen to sixteen they may work ten hours. But this law is very commonly evaded, inasmuch as the regulations which provide that the occupation shall not be continuous and regular, but shall be interrupted by proper intervals, are rendered nugatory by means of various artifices. But even limiting the age to twelve years is not sufficient, and in Switzerland it is made to extend to fourteen years of age. It appears that this limit is necessary, and it will be possible gradually to introduce it here. But furthermore the employment of children in certain of the trades is to be prohibited under all circumstances, and without exception. In cases where children are employed in factories in which arsenic, lead and the like are used, or where the child is exposed to the danger of inhaling dust, it becomes the sacred duty of the legislator to protect the health of the future generation. With regard to women the prospective legislation should enact something as follows: Persons in the second half of gestation shall not be employed in any of the following (or similar) trades; in the manufacture of colored paper containing poisonous compounds, of metachromotypes, of Schweinfurt green, of artificial flowers, or of phosphorus matches; in lace-making, in working sewing-machines, and finally, in general, in all factories and workshops where poisonous gases (carbonic acid, carbonic oxide, sulphuretted hydrogen, sulphuret of carbon), are likely to be developed. No woman recently confined shall be regularly employed in any way in any factory before the ninth day from her confinement. If then she desires to return to her work she must bring a certificate regarding her condition from a competent physician. No woman shall be permitted to work in any of the above detailed employments from the tenth to the forty-second day after confinement.—*Deutsche Versicherungs-Zeitung.*

EXTRAORDINARY LONGEVITY.—The Philadelphia *Evening Bulletin*, of October 1, 1874, contains an obituary notice of George Labar, who died September, in Monroe county, Pennsylvania. According to the *Bulletin*, he was born in the autumn of 1763, in Mount Bethel, now Portland, Northumberland county, Pennsylvania, where his baptismal register is still preserved. He was of French descent, his grandfather having been a fugitive from religious persecution. His father lived to the age of one hundred and five years. In 1870 he had a brother living who was ninety-eight years of age, one sister aged eighty-six, and another aged ninety-two years. He had lived an active out-door life, and had known very little sickness. He used tobacco very freely all his life, both smoking and chewing, but was very moderate in the use of alcoholic liquors. As there seems no reason to doubt the accuracy of the statements given, this is one of the most extraordinary cases of longevity on record.—*N. Y. Medical Journal.*

ON THE DANGERS OF INTRA-RECTAL EXAMINATION.

WITH A CASE.

By ROBERT F. WEIR, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL, ETC.

AMONG the more prominent advances made in surgery during the past few years must be ranked the exploration of the pelvis and abdomen by the introduction of the hand into the rectum. Although this had been practised, or had been suggested, both in this country and abroad, prior to 1872, yet in that year G. Simon, of Heidelberg, set forth in an article which appeared in *Langenbeck's Archiv f. klinische Chirurgie*,* the advantages to be derived by this method of examination. It was immediately recognized as an improvement upon our existing modes of diagnosis, and has since been used by many surgeons of eminence, and thus far, with two † exceptions, without accident. Yet in the original paper of Simon, and more especially in a later article, published by him in the *Deutsche Klinik f. Chirurgie* for November, 1872, he points out clearly the possibility of danger, and at what point it is likely to be encountered. He states, in brief, that he has measured carefully many recta, and finds that the greatest expanding capacity of the intestine is at about 6 or 7 centimetres ‡ above the anus, where it can be stretched from 25 to 30 centimetres. From this point to the superior extremity of the middle third it gradually diminishes to 20-25 cm., and from here it rapidly lessens in circumference until, in the middle of the upper third of the rectum, it does not measure more than 16-18 cm., the narrowest portion being at the beginning of the sigmoid flexure. He also learned that he could rupture the intestine in the cadaver, in this upper part, when forcing his hand, measuring 20 cm., into this portion.

This point, at which the dangerous narrowing begins, is distant from the anus some 12 or 14 cm., and corresponds to the third sacral vertebra, and also to the reflections of the peritoneum, which run forward from the rectum, in the male, to the bladder, and in the female, to the uterus, constituting the lateral boundaries of Douglas's cul-de-sac, and called by Simon the *ligamentum semicircularis Douglasii*.

When the hand, in its greatest circumference, rests at this point, the tips of the fingers can be introduced into the sigmoid flexure, and with the mobility obtained from the extra calibre of the intestine, and from the mesorectum and mesocolon of the sigmoid flexure, palpation may be made in favorable cases as high as "several centimetres above the umbilicus." The limit to the upward motion is due mostly to the check action of the *ligamentum Douglasii*. This, however, is only put on the stretch after the cul-de-sac of Douglas has been everted by the crowding up of the rectum; should the hand be forced still further, not only injury to the intestine and laceration of these peritoneal folds would take place, but probably, as in the experiments made on the dead subject, rupture of the vesical, middle hemorrhoidal, and uterine arteries.

These explorations have not only been repeated

several times in the same patient by Simon himself, but he has also allowed other physicians, with hands of a circumference of 25 to 26 cm., to perform the same manipulations, without any evil results, and, indeed, with but little or no impairment of the tonicity of the sphincter ani muscle, as the next day injections of water could be retained. In his paper he says, to quote his own words: "By a careful observance of the above-given directions (*i.e.*, by proceeding slowly, using a rotatory motion, and avoiding force) repeated experience has taught me, by laying the hand together as a cone, that a bloodless examination may be made with a hand measuring 25 cm. in circumference. In exceptional cases only is it necessary to incise the posterior margin of the sphincter ani muscle."

These views as to the limitation of the extent to which we should endeavor to introduce the hand, have not, however, been received as final, for Nussbaum and Popp* have both been able, by intra-rectal explorations, to touch the ensiform cartilage. Unfortunately for our guidance, the size of the hand is not given.

In this city Dr. C. A. Leale read a paper, in November, 1873, before the Academy of Medicine, on Intra-rector-Abdominal Exploration, and gave a case where, for the purpose of irritating the solar plexus, in poisoning by chloroform, he had safely introduced his hand (twenty centimetres in circumference) to the depth of 16 inches, passing, without doubt, into the descending colon, and had thus recognized by the touch the inferior border of the liver, and projected his fingers forward, so that they could be felt four inches (10 cm.) above the umbilicus. The forearm measured at the point of extreme insertion 25 cm.

In a case of right lumbar colotomy, presented by Dr. H. B. Sands to the New York Pathological Society (MEDICAL RECORD, June 1, '74), the results of a manual exploration of the rectum are given, as obtained by a post-mortem examination. It is there stated that the hand was passed to a distance of twelve inches, and that the forearm was too large to go further, as though the limit of the exploration was the possible dilatation of the anus. The similarity of this case to the one to be described is more striking, by the existence of a laceration of the muscular, but not peritoneal, coat of the rectum, about eight inches from the anus. Dr. Sands's hand, he has informed me, measures less than 19 cm. †

Similar explorations have been made by various surgeons in this city for the diagnosis of a supposed renal tumor, for abdominal aneurism, for intestinal obstruction, etc. In one of these cases there existed a reducible inguinal hernia, which could be distinctly recognized through the wall of the rectum, demonstrating the reasonableness of Nussbaum's suggestion of thus pulling the intestine out of incarcerated hernia, and particularly from those situated in the umbilical region. The hands of the explorers alluded to above did not exceed 19 cm. in circumference. I have thus far purposely dwelt somewhat at length upon the risk that is encountered in these explorations, not only on account of its connection with the following case, but also from being struck by the omission of this

* *Deutsche Klinik f. Chirurg.*, March, 1872.

† Since the above was written an opportunity has been afforded of examining a rectum four days after manual exploration had been resorted to. The case occurred at St. Luke's Hospital, in the service of Dr. T. T. Sabine, whose hand measures less than 19 cm. in circumference. The exploration was instituted for the purpose of establishing the nature of a renal tumor. For this the hand was introduced to a depth of eleven inches, measured from the tips of the fingers. The patient died four days afterwards, and the autopsy showed several ecchymoses on the anterior wall of the upper third of the rectum, and which had resulted from slight lacerations of the muscular coat. The peritoneal and mucous coats were, however, intact.

point in many of the journals in which the procedure has either been described or alluded to.*

CASE.—*Intestinal Obstruction—Stricture of Colon—Intra-rectal Exploration—Right Lumbar Colotomy—Death—Incomplete Rupture of Rectum.*

Elizabeth P., aet. 50, multipara, short and stout in figure, and in apparent good health, summoned me, January 4th of the present year, for the relief of a severe attack of colic, with moderate vomiting and occasional hiccough, which had lasted about forty-eight hours, and had been preceded a week previously by a similar though slighter attack. Pulse 96; temp. 100°. The abdomen was not distended, nor were any hernial protrusions to be felt. Across its upper part was felt the transverse colon, much distended, especially in the right hypochondrium, painless on pressure, and pitting. This could be traced across to the left side, and there was lost to palpation and percussion. Questioning revealed that she had been troubled by a series of colicky paroxysms of varying severity since last spring. They were generally accompanied by moderate constipation, and were without any intercurrent diarrhoea. Her faecal discharges had been for some time past not only insufficient but of a light slate color. She stated that she usually obtained relief from these attacks by domestic purgatives, and in the intervals felt perfectly well. Attributing her attacks to malaria from the want of bilious matter in her stools, she had for this taken large quantities of quinine. The present seizure was the worst she had ever had. She was suffering great pain at the time, but it was not referred to any particular point in the abdomen. A rectal examination detected nothing abnormal. She was directed to take $\frac{1}{2}$ gr. acet. morph. every hour until the pain was relieved, and to have a large injection of warm water and soap suds to be repeated *pro re nata*.

In the course of a few days, Jan. 10th, but not, however, before the vomiting had become stercoraceous, she obtained relief, mainly by the aid of large enemata, and the mass in the colon softened coincidentally with the discharge of the pasty, fluid, clay-colored movements. With alternations of relief and occasional exacerbations of obstructive symptoms, she favorably progressed under the above course of treatment, viz., anodynes whenever the temperature became elevated, large, simple and medicated injections, and occasional gentle purgatives, until February 10; having for several days previously felt quite well and strong, and having daily spontaneous movements, of the same character however. Up to this time, from the persistence of the distention of the transverse colon, lost however in the left hypochondrium, from the amount of fluid frequently injected (three to four pints), and from the depth to which the soft rectal tube was introduced (18-20 inches) by the very intelligent friend who nursed her, her difficulty had been recognized as a case of stricture situated probably in the upper part of the descending colon.

On Wednesday, February 10, a recurrence of vomiting and colic ensued, and no movement of the bowel was obtained by the enema used. A recourse to the previously satisfactory treatment utterly failed to alle-

viate the increasing gravity of the symptoms. On Friday, the 12th instant, stercoraceous vomiting recurred. On the 14th, after an unsuccessful peritoneal injection of four and a half pints of an enema composed mainly of olive oil, during which the rectal tube was carried into its full depth of two feet, it was felt that no delay in resorting to surgical interference should be made—as colotomy was clearly indicated. Inasmuch as in the introduction of the rectal tube a slight obstruction had been felt as its point reached the sigmoid flexure, it was deemed unadvisable to place too much reliance on this means of diagnosis, as the tube might have possibly bent on itself. A rectal exploration was therefore determined upon previous to the operation.

Feb. 15. This plan of procedure was confirmed in a consultation held with Drs. H. B. Sands and W. H. Thompson. The patient, who was in fair condition—pulse 112, temp. 100°—was etherized, placed on side, and the right hand, $22\frac{1}{2}$ cm. in circumference, passed slowly, duly coned into the rectum. It was introduced without difficulty to the entrance of the sigmoid flexure, which was entered by the tips of two fingers. The intestine at this point was apparently healthy. With the hand in this position the lower border of the left kidney was readily recognized, the aorta a short distance above its bifurcation, and to the right the distended *caput coli* indistinctly felt.

The hand was then withdrawn, having been inserted to a depth of eleven inches by measurement. The possibility of disease of the sigmoid flexure had alone been excluded by the exploration. Dr. Sands's subsequent similar examination (hand of 19 cm.) only confirmed this statement. The results of the injections and introduction of the rectal tube, therefore, were entitled to full weight in determining the opening to be made in the ascending colon in the right side. It was noticed that during the rectal explorations the patient was much depressed, pulse feeble, surface pale, but respiration regular; so much change was manifested that it was suggested by one of the consultants that a fatty heart perhaps existed. By removing the ether and administering stimulants these symptoms soon passed off. They were probably due, as was afterwards shown, to the laceration of the intestine. Having rallied satisfactorily, the colon was reached by Bryant's oblique incision. Not, however, without first encountering the lower edge of the kidney, from which rehearsal on the cadaver had taught that the intestine could be found by going directly forwards. The gut was opened longitudinally, and about two quarts of fluid, light-colored faeces flowed out with relief to the somewhat tense abdomen. The intestine was stitched to the skin, and the balance of the wound loosely stuffed with carbolized lint. The opening was recognized to have been made at the angle formed by the ascending and transverse colon. The patient was greatly shocked by the operation, but by careful attention and by use of stimulants and heat, by 6 P.M. reaction was fairly established, the operation having been performed at 3 P.M.

She, however, gradually sank during the evening, and died at 2 A.M. Feb. 16.

The autopsy revealed the existence of a narrow band-like stricture at the middle of the transverse colon, admitting only the tip of the little finger, and formed by a growth in the walls of the intestine, and of a character yet undetermined. Above the stricture, in the fluid contained in the colon, was found an orange pit, coated lightly with hardened faeces. As this was the only solid body found, it was inferred that it might have occasioned the final obstruction. The gall-bladder

* The danger is not referred to in the excerpts found in the following journals:

1. *Gazette Hebdomadaire*, No. 1, 1873.
2. *London Medical Record*, Feb. 12, 1873.
3. *Am. Jour. Med. Sciences*, April, 1873.
4. *Ranking's Abstract*, July, 1874.

And even in the *London Med. Record*, Aug. 26, 1873, which condenses an excellent translation of Simon's entire second article from the *Cincinnati Lancet and Observer*, May, 1873.

was distended by reason of a large calculus plugging up its outlet. No adhesions existed here to indicate the escape by ulceration of a similar calculus, and consequent formation of the stricture. The liver and kidneys were in a state of fatty degeneration, but the heart was normal.

On raising up the small intestine from the pelvis about two teaspoonfuls of free blood was found in Douglas' cul-de-sac, and running from the level of the sacro-iliac synchondrosis to the bottom of the cul-de-sac, was seen, on the anterior aspect of the rectum, a rent involving the muscular and peritoneal coats. This longitudinal rent was really divided into two by an interposing band of longitudinal muscular fibres, but the ruptures had evidently been produced at one time.

The mucous membrane was intact, though congested and ecchymotic, from the anus nearly to the sigmoid flexure, which latter was quite small in size.

The portion of the colon showing the artificial anus and stricture, with the rectum, were sent to the Museum of the Roosevelt Hospital.

In concluding the remarks upon this case, it will be recollected that the hand was introduced to a distance of 11 inches, measured from the tips of the extended fingers—the fingers themselves measuring 4 inches, and although no force was supposed to have been used, yet the unconscious action of the wedge-shaped fingers must have been considerable.

Now the depth given by Simon to Douglas' ligament is 12-14 cm., on adding to this 5 cm., as the average mobility of the parts upwards, we have a total of 17-19 cm., as the distance beyond which it is inadvisable in general terms to introduce the greatest circumference of the hand, or, in other words, the hand can be safely introduced, if below 10½ inches in circumference, to a depth of from 7 to 7½ inches, measured from the knuckles. Such is the rule I should formulate, as it has been seen in Sands' case that a hand of 19 cm. inflicted injury.

It is worthy of remembrance that the erect position has been found by Dr. Peaslee to bring organs within reach that would otherwise be beyond palpation.

In examination for supposed stricture the degeneration of the muscular fibres from long disuse should be taken into consideration, as the friability of the intestinal walls is thereby often increased. As to what influence the lesion would have had in the subsequent progress of the case, had the patient survived, it can only be surmised. However, had the mucous membrane yielded to inflammatory necrosis, there would have been no reason to fear fecal extravasation.

The case, in addition, corroborates, I think, very markedly the usefulness of enemata in the diagnosis of obstruction of the large intestine. Brinton, in his work on Intestinal Obstruction, calls attention to the importance of this means, and estimates that the large intestine would hold nine pints of fluid. This statement is here confirmed, the stricture being in the centre of the transverse colon and the intestine below it having a capacity of 4½ pints. A case of stricture of the upper part of the sigmoid flexure was satisfactorily diagnosed, a few years since, in my service at St. Luke's Hospital, by the injection of three pints of fluid, after having ascertained previously that the fluid did not pass through the stenosed portion of the intestine.

This remark recalls the fact which was demonstrated in the present case, as well as in others, and recently set forth by Dr. Battley, of Georgia, that injections can be forced from the anus out through the mouth.

TRANSPLANTATION OF RABBIT'S CONJUNCTIVA FOR CURE OF SYMBLEPHARON.

FAILURE OF THE OPERATION—SUBSEQUENT SUCCESSFUL AUTOPLASTIC OPERATIONS.

By GEORGE E. POST, M.D.,

PROFESSOR OF SURGERY IN SYRIAN PROTESTANT COLLEGE AT BEIRUT.

SABA, aetat 25, had been under treatment for many months by a German surgeon for symblepharon. The deformity was as follows: The conjunctiva of the outer and lower aspect of the globe, and the corresponding lining of the lids had been lost, as the result of sloughing, and the globe was adherent by one-fourth of its periphery to the outer canthus. The cicatricial band was thick, red, and prominent, preventing the closure of the lids, and the cornea, closely tied by its outer margin to the external canthus, was in a state of pannus from exposure to the sun and air.

The treatment previously adopted had consisted in the passage of a silver wire through the thickness of the connecting membrane, in the hope that a fistulous track would be formed in the space between the globe and the bases of the lids, and that a subsequent incision would liberate the globe, and restore its mobility.

On the admission of the patient to St. John's Hospital, the attempt was twice made to supply the lost conjunctiva from a living rabbit, in the following manner: The rabbit being chloroformed, threads, each armed with two needles, were passed around the margin of a patch of conjunctiva, about the size of a nickel cent. These threads were passed at a distance of about a fifth of an inch from each other, around the whole circumference of the patch, half of which was ocular and the other half palpebral. The patient was in the meantime chloroformed, and the lid separated from the globe, and, all being now ready for the transplantation, the flaps were rapidly dissected from the rabbit's eye, and transferred to that of the patient. The coaptation was made very exact, and the eye dressed with picked lint and an elastic flannel bandage, as is my invariable practice after these operations. I have long since eschewed wet applications, as positively hindering the healing process, and irritating rather than soothing the parts. The whole of the transplanted flap sloughed, excepting a strip a line in width at the tarsal margin. A second attempt met with a similar result.

I now determined to transplant skin into the conjunctival sac. The operation was divided into several sessions.

SESSION 1ST.—A flap of skin was taken from the cheek by cutting from the outer canthus downwards and inwards to the lowest part of the malar bone. The knife was then carried outwards a third of an inch, and then turned upwards and outwards until the incision reached a point three-fifths of an inch exterior to the external canthus, and on a level with it. The flap of skin was then dissected up from the subjacent tissues. One blade of a pair of probe-pointed scissors was now passed vertically behind the lower lid in such a way that its point was at the bottom of the conjunctival sac at the inner margin of the membrane of adhesion, and its cutting edge directed outwardly towards the canthus, while the other blade was placed on the canthus. On closing the scissors, the cicatricial band was divided to the level of the canthus, and with it the tarsal cartilage, and the remaining tissues of the eyelid, so that its outer third could be easily lifted away from the globe. The outer inferior

margin of the flap was then attached to the tarsal margin, and its inner superior border was made to dip down into the space between the lid and the globe in the following manner: Threads, each bearing two needles, were inserted near its margin, and the opposite ends carried by their respective needles through the thickness of the lid from the base of its inner aspect to its cutaneous surface, where they were tied over a little piece of lint. By this process the raw surface of the transplanted flap was applied to the inner surface of the lid, while its inverted cutaneous surface was turned towards the globe, and served to replace the lost conjunctiva of the lid. The base of the flap was slightly twisted. The lips of the wound in the cheek were brought together by pins and sutures, and the orbit covered with lint, and bound with a flannel roller. Union of the flap in its new position took place throughout its whole extent, and no irritation was experienced from the intrusion of a cutaneous surface into the conjunctival sac. As the result of this operation, the outer canthus was much widened, the outer extremity of the inferior tarsal margin being separated from its fellow of the upper lid by the thickness of the intervening inverted flap. The corner was now free from the inferior lid, and the lining of that lid was of nearly normal breadth.

SESSION 2D.—A similar operation was now performed on the upper lid, the flap being taken from the temple in the following manner: An incision was made from the outer extremity of the superior tarsal margin (where outer canthus had been) directly upwards for the distance of an inch. The knife was now turned outwards, and carried a third of an inch horizontally, and then turned downwards and slightly outwards, and the incision completed to a point three-fifths of an inch exterior to the canthus, on a level with the tarsal border. The band of adhesion between the upper lid and the globe was now divided, as before described for the lower lid, and with it also the thickness of the upper lid. The flap, being dissected from its subjacent attachments, was now inverted and secured to the lid as before mentioned. The transplanted skin adhered throughout, and the cornea was thus liberated from the canthus, the angle of which was now widely separated by the two flaps of skin. The thick fleshy mass of adventitious connective tissue, which had united the globe with the lids was now rolled together into a band like a pterygium, stretching from the corneal border to the junction of the bases of the transplanted flaps, which constituted the new canthus. This new canthus being bunched and unsightly, owing to the twisting of the bases of the flaps, and both lids having a tendency to eversion, owing to the severing of the orbicularis muscle, a third operation was necessary to give symmetry to the external commissure.

SESSION 3D.—After a period of two months from the last operation, in order to give time for the establishment of the nutrition of the transplanted flaps, the redundant projections were removed by cutting from the base of each flap an elliptical horizontal segment, half an inch in length by a quarter of an inch in breadth, in such a manner that the outer angles of the two denuded surfaces met, while their inner angles were separated by a third of an inch of skin, half of it from the lower flap and half from the upper. The denuded surfaces were now brought into apposition, and retained by twisted sutures. Union took place, and the result was a well-formed ocular apparatus, with a simply nebulous cornea, and an external pterygium, which is slowly diminishing in size, and which may be removed by a future operation.

THE CLINICAL THERMOSCOPE.

By EDWARD SEGUIN, M.D.

(A paper read before the New York State Medical Society, Feb. 3, 1875).

This little instrument is a simple application to medical diagnosis of the principles of physics on which Rumford and Leslie constructed their differential thermometer.

The clinical thermoscope is a glass tube, T, a quarter of a line bore, seven inches long, closed at one end by a bulb, B, nine lines in diameter, and open at the other end mouth-like, M, by a delicate enlargement of the rod. In this state it contains nothing but air.

To make the thermoscope ready for clinical use, the bulb is heated over a lamp or fire, sooner in a bowl of hot water, and when the air contained in the bulb is dilated a few degrees above the ambient temperature, the open end is quickly plunged in—an inch deep—and quickly withdrawn from another bowl of cold water. The drop or two, which will have then entered the mouth, is seen to run up the tube. If it stops near the bulb, it will be the index of the thermoscope. If it stops higher, say two or three inches from the mouth or if it runs into the bulb, the latter was too cold or too hot, we have to jerk away that drop of water and recommence: three or four trials to obtain a good water-index take hardly a minute.

In this condition, the air contained behind the water-index makes itself isothermal to the ambient temperature, and the thermoscope is ready.

It is applied—I do not say introduced—like the fever or surface thermometers, wherever an anomaly of calorificity is known or suspected. Its habitual place (*lieu d'élection*) is not however the axilla, it is the closed hand.

In five to ten seconds the index has attained the maximum height or fall, of any significance.

To read it, we mark the starting-point of the index, the terminus of its course, and the time (in seconds) to reach it.

To take more mathematical observations, a movable scale is attached to the stem, and made to slide, in order to put its lowest figure on a level with the head of the water-index; so that the thermoscope is always correct—that is more than can be said of most of our clinical thermometers.

But with, or without a scale, it gives by contact indications (*a*) at the start, of the volume of heat escaping by radiation (*b*), at the end of its course, of the *portée* or reach of its velocity; whilst without contact, by gently blowing on the bulb, it shows the degree of combustion which takes place in the lungs, and other phenomena of heat which I have no place to explain.

Without a scale, a mother can tell at what hour the index rose quicker and higher, or quicker only, and not so high, etc. Without a scale, too, a physician who well knows his case, and is short of time, can, in less than ten seconds, decide upon the dynamic conditions of the next twelve or twenty-four hours, dependent on the waste of calorificity by radiation—that is to say, life itself in many cases—and prescribe accordingly.

The thermoscope may often be called to decide about

the precise seat of an affection indicated only by general, reflex, or regional symptoms.—For a few days a business man felt dispirited, good for nothing, no hunger, no thirst, no true sleep; complained of cephalalgia, nausea, hypogastric pains. The fifth day he remained in bed and had several shivers. Seen in the evening, appearance prostrate, pulse 85, temperature 1 (one centigrade degree above the normal). The family were whispering fears of typhoid fever. This 1 (equal to 100.4° F.) could hardly be found the second evening of the abdominal typhus, but the fifth! Manual examination discovered nothing, the thermoscope revealed no difference of radiation between the right and left iliac regions; but proved a decided rise (half an inch) on the right of, and above the pubes. This indication was trusted; warm fomentation *in situ* of a decoction of digitalis leaves and elder blossoms, warm drinks and 5 gr. Dover powder brought on an abundant diuresis and a profound sleep, followed by an early start for business. What an opening for medication, if the thermometer had not told what the disease was not, and if the delicate thermoscopy had not limited the sick organ in the painful region!

Besides this daily use, the thermoscope criticises and comments some of the rare enigmatic findings of the clinical thermometer.—I was called to a man who had fallen from a three-story hatchway. I found a compound fracture of one leg, and a fracture of the skull; rather insensible to pain, full consciousness, jactitation, with a speck of erotism, pulse confused, temperature 98.5° F.; in other terms, at the point of perfect health. Was it derision or delusion? Neither; it was a compound temperature whose component elements escaped the fever-thermometer.

I tried the thermoscope. Put in the hand it rose, in the axilla it rose more, below the sternum it rose less, in the inner angle of the eye it fell rapidly. The thermoscope had discovered the point where extravasated blood was coagulating, at the base of the brain. Thus became comprehensible that sardonic 98.5° F. = perfect health in a dying man, as a compound temperature, whose composition could be schematically approximated by these figures: 100.3° F. of general pyrexia, balanced by 96.7° F. of hemorrhagic apyrexia, equals 98.5° F. This thermoscopic analysis saved the man further painful manipulations, and he died, as predicted, inside of three hours.

If we pass from the sick chamber to the death-slab, the thermoscope will prove to be yet the only "necrometer" founded upon the radiation of vital temperature; notwithstanding the joke practised on the Paris Academy of Medicine, to which *my* physiological thermometer was presented by M. Bouchut, as a necrometer, after displacing the zero from the point of health to a fanciful point of death.

To test the necroscopic power of my new instrument, I repaired to the Bellevue Hospital of this city. By the courtesy of Dr. E. Janeway, I was shown in the dead house, about noon, the body of a young woman brought in at 9 A. M. The thermoscope being applied below the sternum, its index did not move from the position it had taken in the ambient temperature of a very cold January day; but put in the axilla, it slowly and steadily rose about 6 centim. = 2 inches. A thermometer inserted instead, and kept in the same axilla fully ten minutes did not perceptibly move.

So the thermoscope, in contact with the living, shows the activity of their calorificity; and in contact with the dead, it ceases to indicate heat only when and where organic combustion becomes progressively extinct.

As thousands are, and have been buried alive, the invention of a true "necrometer" excites a deep interest, increased, if possible, since cremation is mooted. For some have knocked at their coffin and re-entered the world; but of what use would it be to knock for help inside the furnace? The proof of death is wanted now more than ever, and if I am not mistaken the thermoscope gives it.

I give this simple and costless instrument to my confrères, as I gave seven years ago, in THE MEDICAL RECORD, the "physiological thermometer;" begging them to try it in the spirit of candor which made Biot say: "We must not shun the humblest contrivances, when they can improve or supplement the *medical senses*."

N. Y., 17 E. 21st St.

A CONTRIBUTION TO THE TREATMENT OF EPISTAXIS.

By BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPARTMENT OF THE THROAT), ETC.

EPISTAXIS is no infrequent trouble. At times it may be of slight importance, either because its efficient cause is ephemeral in nature, or else the loss of blood from the nasal passages is rather a fortunate circumstance than one to be regretted.

When, however, the patient is weak and laboring under some general diathetic dyscrasia, or when the epistaxis becomes abundant and the cause of it is obscure, we shall then have a condition of things which almost of necessity occasions solicitude.

Our desire and duty become in an equal degree imperative to employ surely and rapidly such means as we may be able to utilize in order to arrest bleeding.

Generally speaking, recourse is had to cold, topically applied, and the employment of some one of the various mineral or vegetable astringents.

Simultaneously, or at a later period, drugs having a special corroborant or styptic action are prescribed to be taken by the mouth.

To these have been added, within a brief period, those medicaments which act through the vaso-motor nerves, and tend to contract vascular walls. If all the above means fail of success, posterior, or both posterior and anterior plugging of the nasal passages is considered and frequently put into execution.

What the trouble to the physician is, how great must be the annoyance and unpleasantness to the patient who submits to the operation we all know, either from our own experience or that of others. Besides, we are aware that it is only by care in the timely removal or renewal of the plugs that we can surely avoid certain attendant risks of septicæmia. Any mode of treatment, therefore, which has been adopted, when the agents usually employed have proved to be inefficacious, and has been productive of the happiest results, will, we doubt not, receive a welcome from our colleagues.

Such a case, where obstinate bleeding was completely arrested by compression of the facial arteries, we shall now relate:

CASE.—R. S., aged 62, medium constitution, residing in Savannah, Georgia, came to New York City, and was received as an in-patient at the Manhattan Eye and Ear Hospital, September 4th, 1874, to be treated for cataract. A few days later, a successful operation was performed by Dr. Cornelius R. Agnew upon the affected eye, and during the first week of November,

the patient had recovered from the effects of the operation, and had obtained permission to return home. While out walking, November 11th, our patient was suddenly attacked with bleeding from the nose. The loss of blood at this time was quite abundant, and from November 11th to November 20th, notwithstanding the use of ordinary agents to arrest bleeding, the epistaxis frequently recurred during day and night. Finally, the condition of the patient was such as to occasion much anxiety both to herself and her medical attendants. Local applications of the astringent sort, had been freely used, and these (alum, tannin, etc.), were insufflated, under the form of powder, into the nasal passages, and also employed in strong solution by means of the posterior nasal syringe. Cold compresses upon the nose and forehead were also tried, and the patient was placed in a room at a somewhat lowered temperature.

By the application of the topics above mentioned, clots were formed in the nasal passages, and the bleeding stopped temporarily. In a few hours, however, oozing of blood took place about the margin of the anterior clots (especially the one on the left side), and between them and the *alae* of the nose.

Two days after this mere local treatment was begun large doses of quinine, given internally, were added to it. And this was done for two reasons:

1st. Because the patient informed us that she had had a severe attack of malarial fever six years previously, and since that time occasionally experienced chilly sensations which she attributed to this poisoning.

2d. We believe that from the well-known action of sulphate of quinine to contract or lessen the calibre of small vessels, we might fairly hope it would be of service.

Unfortunately we were deceived in our anticipations, and though we gave as much as thirty grains of quinine in eighteen hours, and continued it during three days, it remained without appreciable effect. We were prevented from still further increasing the dose by very unpleasant symptoms of giddiness and buzzing in the ears.

On Nov. 16th large doses of tincture of the chloride of iron (30 gtt.), combined with small doses of quinine (2 gr.) were prescribed to be taken every four hours; also similar doses of fluid extract of ergot (*viz.*, 30 gtt.) every four hours, with the injunction that the ergot should be given two hours before or after the exhibition of the iron and quinine. In this way the patient would not be more than two hours, except during those of sleep, without taking medicine internally.

The styptic and tonic action of the iron, as well as the influence of ergot on the vaso-motor nerves, and through them on muscular fibre, remained equally inefficacious. After two or three days of the above treatment, the clots were washed from the nasal passages, and plugging by means of the India-rubber bag, as recommended by Salvatore Caro, M.D. (*vide Med. Record*, August 15th, 1874), was attempted.

This method proved equally fruitless with what had already been tried in stopping the flow of blood.

We now commenced, whilst continuing the use of iron, quinine, and ergot as above, compression of the facial arteries upon the superior maxillary bones, just before they reach the *alae* of the nose, by means of two small pads made of lint. These were sewed to a piece of tape at the proper distance from one another, and the ends of the tape were passed across the cheeks and above the ears, and tied securely behind the occipital bone.

This treatment achieved the happiest consequences, as will be seen from the following notes:

November 22d. Patient continues to take fluid extract of ergot and tincture of iron with small doses of quinine. Compression of facial arteries almost ceasing since first applied. On one occasion only the tape and pads were removed in order to ease the patient, who complained somewhat of the discomfort caused by them, and the bleeding immediately recommenced. General condition improved; patient stronger and less anxious.

Treatment.—Continue iron and quinine, and pressure with pads on facial arteries; nourishing food; discontinue ergot.

Nov. 24th. Patient continues to improve in strength and morale. So soon, however, as she takes pressure off facial arteries bleeding reoccurs.

Nov. 30th. Bleeding has stopped altogether for several days. Patient left hospital.

We do not, of course, believe that by compression of the facial arteries we shall be able to arrest all cases of bleeding from the nose. We trust, however, it may frequently be adjoined to other treatment with marked benefit to our patient, and by itself may prove of the greatest utility in exceptional circumstances where other means are not at hand. For, in point of fact, it is from the septum that takes origin many of our worst cases of epistaxis, and it is this portion of the nasal passages which receives its arteries mainly from the terminal branches of the facial. By compression of the arterial trunk we must, of course, greatly diminish, if we do not stop absolutely, the afferent blood flow.

This treatment, then, is *rational*, and whenever experience is capped by reason we are better satisfied with, and more willing to accept, it.

A word with respect to the instrument described and landed by Dr. Salvatore Caro, and to which we make reference in the history of our case. We regret to say that in our hands this instrument did not work satisfactorily, and for the following reasons:

1. When *air* is blown in by the tube the bag dilates unequally, and, besides, dilates either more or less than we desire.

And further, we have no means of accurately determining how much the bag has in reality dilated, except our tactile sensations, which are furnished by the right index finger passed behind the velum. Of course if the inflated bag should come into contact with the pharynx, where we are able to see it, *gagging* is, of necessity, immediately occasioned.

2. The sides of the catheter attached to the bag are too *firm*, and when we used pressure on them with the fingers, or by means of a cord tightly tied, so as to prevent the return of the air blown into the bag, we found it impossible to accomplish our object.

3. Owing to its unequal dilatation, the bag is apt to give way in some particular point, and allow the air to escape, and consequently the sides of the bag to collapse. Are these objections avoidable? We believe they are, if the following indications be carried out:

1. The bag should be made of rubber, which shall dilate *equally*, and the amount of dilatation to be given may be limited by an outer covering to the bag, which is inelastic and sufficiently strong to resist a certain amount of interior pressure.

This outer bag should have a capacity, when expanded, somewhat superior to the dimensions of the posterior nares, and be made of some very light, smooth material.

2. The conductor-tube should have a faucet attached to it near its distal extremity, so that the air or water

could be shut up in the bag as soon as it is filled with either one of these fluids.*

15 WEST 26TH STREET, March, 1875.

TWO CASES OF SYMPATHETIC DISEASE FOLLOWING LONG STANDING PENETRATING WOUNDS AND LODGEMENT OF FOREIGN BODIES IN THE EYE.

By WM. SHAW BOWEN, M.D.,

OPHTHALMIC AND AURAL SURGEON TO THE HARTFORD HOSPITAL.

CASE I.—Mr. W., *ret.* 51; vision was lost in the left eye seventeen years ago, by the penetration of a spicula of metal impinged against the cornea with force from a drop press.

Severe pain and inflammation followed, and in the course of a week it was discovered that vision had wholly disappeared.

Patient was first seen June 30, 1874. The left eye was normal in size, a small macula at the inner side of cornea. Ciliary redness in a marked and limited zone; iris disorganized, of a reddish-brown hue; aphakia and iridodonesis. Tension—1 of Bowman. Fundus obscured by reddish-brown reflex on examination with the ophthalmoscope. The right eye shows an injected ciliary zone, tender on digital pressure, and a discolored iris. Complains of photophobia and lachrymation. $V = \frac{1}{2}\%$. Optic disk, hyperæmic; marked choroidal congestion, especially in the region of the macula.

Patient is depressed and despondent; cannot pursue his business. Immediate enucleation advised, and performed; the eye was placed in Müller's fluid immediately afterwards. Tonics of iron, quinine, and cod-liver oil; Huerteloup's artificial leech applied to the temple.

Sept. 10. Ciliary redness entirely gone. Has had slightly increased choroidal trouble since the enucleation, but is now free from photophobia and pain. $V = \frac{3}{10}\%$; general health much improved. Attends to his business.

The eye was removed from Müller's fluid September 30th, and laid open. Choroid degenerated; vitreous filled with flocculent matter; retina separated almost its whole extent by hemorrhage from the choroid.

The spicula of metal, $2\frac{1}{2}$ mm. long and 1 mm. in diameter, was found impacted in the optic disk, about 1" from the outer end of its horizontal meridian, and so firmly lodged that traction was necessary to dislodge it. No traces of lens capsule. Ciliary body in an inflammatory state.

As long ago as 1862, Pagenstecher considered (*Klinische Beobachtungen*, Heft 11, p. 49) that the irritation leading to inflammation is conducted through the sympathetic system; and remarked that independently of the optic as a nerve of special sense propagating an injurious influence in a retrogressive direction, the primary effects of the sympathetic ophthalmia would under such circumstances appear in the retina and not in the choroid. The above case affords a good instance of injury to the great nerve itself, and the sympathetic inflammatory disturbance deferred for an exceedingly long period of time, almost exceptional in length of duration, and then excited into a flame only when the uveal tract was thoroughly diseased and disorganized.

CASE II.—Mr. G., *ret.* 42, blacksmith, nine years ago was struck by a piece of iron from an anvil, at the inner sclero-corneal junction of the right eye. At the time of the receipt of the injury he was uncertain whether the metal passed into the globe or not. Severe pain and inflammation followed, and he was confined in a dark room for seven weeks. At the expiration of this time $V = 0$ in the injured eye. Has pursued his occupation since without annoyance, save occasional attacks of neuralgia of the globe and eyebrow, and slight redness of the globe, and conjunctiva of the lids. Left eye free from trouble of any kind until August last, when the patient experienced intermitting pain with photophobia. The injured eye at the same time showed ciliary injection, and was painful to the touch. On inspection the right eye was normal in size, a marked ring of ciliary redness; the iris reddish brown, and tremulous at the inner side; pupil moderately dilated. Aqueous somewhat turbid. Tension normal. Left eye normal externally. On dilatation with atropine the ophthalmoscope revealed sympathetic disease. A moderate atrophic crescent at the outer border of disc; choroid hyperæmic. Intolerance of light so great as to require the use of a smoked glass ophthalmoscopic mirror. $V = \frac{1}{10}\%$.

Immediate enucleation of the injured eye advised, and performed the following day under æther: the globe was placed in Müller's fluid. Sympathetic disturbance entirely disappeared in a week, with the aid of iron, quinine, and the artificial leech. After remaining in the hardening fluid five weeks, the globe was opened by an incision through its vertical axis. The retina intact; vitreous turbid, filled with flocculent matter. The lens was displaced to the outer side of globe, opposite the point of penetration of the foreign body, and at this point the ciliary body was enormously enlarged, measuring five mm. in thickness. The choroid attenuated, and in one place, near the ora serrata on the inner side, beneath the internal rectus muscle, was gelatinous, with a flake of blood between it and the sclerotic.

Iris attenuated and friable. The fragment of iron was not to be found until the ciliary body was laid open, and a bit of metal as large as the head of a small pin was imbedded in its fibres.

This case is remarkable from the nature of the injury, and from the length of time that ensued between the primary wound of the ciliary body and the commencement of the sympathetic irritation of the opposite eye. A foreign body occasionally may remain in the globe many years without unpleasant sequelæ in the other organ of vision; but the literature of ophthalmology does not, so far as can be ascertained, afford a similar instance of the penetrating substance remaining for so long a time encysted in the tissue of the ciliary muscle without sympathetic irritation and disease of the fellow eye.

That the ciliary nerves are the medium of propagation, there is no doubt, and an injury to the place of distribution of those nerves of course would act as an immediate irritant, and the effects of this irritation usually appears after a short interval of time in the opposite organ.

The point of puncture, and its neighborhood, had been tender and painful for weeks prior to the commencement of disease in the left eye, and the patient was urged in vain to submit to the procedure of Dr. Meyer, who has successfully divided the fibres of the ciliary nerves at the point where the sensitiveness is localized.—(*Annales d'Oculistique*, Sept., 1867.)

HARTFORD, CONN., Feb. 3d, 1875.

* Such an arrangement is, we are informed, figured in Ziemssen's New Cyclope of the Practice of Medicine, in the chapter on Disease of the Nasal Passages.

Progress of Medical Science.

HUETER ON THE RELATIONS BETWEEN SCROFULA AND TUBERCULOSIS.—Professor Hueter of Greifswald published some time ago an interesting and ingenious theory explaining the nature of the two pathological conditions, scrofula and tuberculosis, and their relations to one another. These views have met with comparatively little notice, though they appear valuable, as tending to shed light on obscure subjects.

Hueter states that *scrofula is the soil in which tuberculosis is produced*, and upon this proposition he bases his theory and practice.

He does not attempt to describe the meaning of the terms scrofula and tuberculosis, but gives a general picture of them and develops his picture as follows, though it is confessedly hypothetical. Our protection, he says, from the various sources of inflammatory irritation with which we are surrounded, especially those suspended in the air, depends upon the epidermic and epithelial coats of our skin and mucous membranes. Let us suppose, then, he adds, the case of an individual in whom this protecting coat is not perfect but presents numerous interspaces or breaks, the little pores which the microscope has shown to exist between the epidermic and epithelial cells. Such an individual would be especially susceptible to external influences, because he offers ample opportunities for the entrance of disease germs. He may therefore be called very "irritable" or "vulnerable," which increased vulnerability and irritability however cannot be considered as exactly corresponding to our conception of scrofula, and still they are to be regarded as lying at the basis of scrofula. Following closely upon this fact he observes that we recognize in inflammations of scrofulous patients a tendency towards extension both in space and time. We call a person scrofulous when inflammations extend from place to place upon his body, and when they are cured with difficulty or only after a long time. Such phenomena our author feels justified in assuming to be connected with the degree of development of the plasmatic system, to which the pores of the rete Mulpighii, already referred to, likewise belong. Accordingly, the greater development of this system in childhood as compared with adult life teaches us the reason that scrofula is so pre-eminently a disease of that period, and so the expressions a "pasty" or "spongy" look, a "lymphatic" constitution, etc., are warranted by anatomical facts. In the next place, tracing the irritating particles and their inflammatory products into the lymphatics and associated lymphatic glands, he declares that "lymphadenitis is one result, but not the first expression of scrofula." He regards the cheesy metamorphosis of the lymphatic glands, which is the next feature observed, as the result of a continuous, slight irritation produced by these particles, and he agrees with Billroth in the opinion that the cheesy portions do not, as a rule, result from pre-existing abscesses, but are merely the cells left crowded together, from which the fluids have drained away owing to the incomplete circulation of the lymph in the affected glands. As he follows up the successive manifestations of the scrofulous affection his next statement is that scrofula begins with the local inflammations which are seated on the peripheral side of the lymphatic glands, and which finally culminates in the cheesy infiltration of these glands, and this is the first indication of a danger involving the life of

the individual. The pre-existing inflammations may, of course, have jeopardized the functions or integrity of the organs where they occurred. He feels compelled to answer almost positively in the negative the question whether these cheesy infiltrations may terminate in resolution. Though not outside of the limits of possibility, such an issue is extremely improbable. After months or perhaps years of passive inactivity the cheesy infiltration, as a result of some new irritation, becomes the seat of a subacute suppuration, which is most commonly found in the peripheral layers of the glands. These abscesses are apt to be subcutaneous, and to break externally, and thus sometimes a cure is effected. And now we come to the important question of how scrofula passes into tuberculosis, for at some time after the development of the cheesy infiltrations, we are likely to observe hectic fever, and all that group of objective symptoms which are known to be characteristic of the latter disease. Hueter rests his explanation chiefly upon the experiments of Fränkel and Cohnheim. It is that the finely granular detritus of the cheesy infiltrations, when the plasmatic channels and lymphatics are opened by the occurrence of suppuration, is set free, and finds its way through the blood-vessels into the lungs, and finally into the general circulation. These granules ultimately become lodged either in some capillary blood-vessels or lymphatic, and form there minute emboli, around which the white blood-corpuscles collect, and we thus have miliary tubercles. The process is, in fact, a pyæmia, with innumerable minute inflammatory metastases. This explanation derives support from the clinical observation that the suppuration of the cheesy focus generally precedes the development of miliary tubercle. Coming now to speak of treatment, our author insists upon the importance of the well-known anti-scrofulous general treatment, and upon suitable attention to local inflammations. Moderate enlargements of the lymphatic glands will often yield to general treatment; but when these are as large as a pigeon's egg or hen's egg, and obstinate, he protests against further delay, and urges their *extirpation by the knife*. The glands most likely to require the operation are the submaxillary group, those on the anterior and posterior borders of the sterno-cleido-mastoid, and those under the chin. He considers the operation free from danger in the hands of a competent surgeon, and believes that it is most urgently demanded so soon as suppuration occurs in the glands which are the seat of cheesy infiltration, and that the least which even a timid practitioner should do would be to lay open the abscess freely, so as to allow the broken-down cheesy matters to escape. He urges the application of the same principles of treatment to scrofulous inflammation of the testicle and epididymis, and also to that of the bones and joints of the extremities. In the latter he therefore practises resection of the joints, or he opens and removes the osteomyelitic foci. — *Volkman's Sammlung klin. Vorträge*, No. 49.

VACCINATION IN ROME.—In January last the Provincial Sanitary Council of Rome, finding that animal vaccination in Rome and in the entire province was unsuccessful, unanimously urged the Minister of the Interior to nominate one of its members as the provisional conservator of vaccine for the commune of Rome. The minister has given notice to the Prefect of Rome, that, in the official vaccinations in the province, animal lymph is to be abandoned, and humanized lymph used as was formerly done.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 20, 1875.

THE MEDICAL CHARITY SYSTEM OF IRELAND.

In a previous number we remarked upon the means which might be taken to discriminate in the dispensation of our medical charity to the sick poor. Although we do not pretend to have exhausted the subject, the suggestions which have been offered are, perhaps, well suited to the circumstances of the government of the various charitable institutions. It is true that the management of each of these charities is different, but in the main there does not appear to be any danger of militating against any important regulation by adopting the simple plan which we have proposed.

Naturally following the discussion of the best means to insure the greatest good to the recipients of the services of these institutions, is the question concerning the pecuniary capabilities of the institutions themselves. As a rule, most, if not all, of these institutions are behindhand in funds necessary for their support. Even with some of the older ones it seems to be a question of time and exertion how long they can continue the performances of their good offices. The burden of their support is oftentimes very unequally borne by a few benevolent individuals, who, rather than see the institutions fail, not only liberally contribute themselves, but make the most strenuous efforts in the direction of begging from others. This is not as it should be, but how to remedy the difficulty is a question which has been earnestly and thoughtfully considered by all interested in the continued prosperity of these necessary means of charity. It is with the greatest difficulty that any appropriation can be obtained from the Legislature; in fact, there is as much effort to secure them, as much influence brought to bear as in lobbying through the schemes of selfish speculators or heartless monopolists. Very often, too, in spite of the best directed efforts, a failure to secure any aid whatever is almost a foregone conclusion. So long as we make these matters a subject of supplication this will

doubtless always be the case. Until the managers can claim such appropriations as a matter of right, we can hardly expect any change for the better. The way to have such a claim well established is to secure the enactment of a law for the proper care of the sick poor, and relieve the managers of the responsibility of maintaining from year to year a healthy solvency of their institutions.

In regard to the effective working of a law having this end in view, we can learn a great deal from the experience of other countries, and particularly that of Ireland. This country can afford the best example of what can be accomplished by well-organized charities, because it is generally considered to be the poorest in Europe. Notwithstanding this fact, the publicly relieved pauperism of Ireland has, during the past five years, been only thirteen per thousand of the population, while that of England has been as high as forty-six per thousand. This difference in the pauper rate is largely due to the dispensary system which exists in Ireland, but which does not exist in England. As a system it is a model, and in consideration of some of the means to be taken to secure a reform in our own institutions we cannot do better than refer to some of the provisions. The law in question has at least the merit of having been thoroughly and satisfactorily tested, and if it does not serve as a guide to a prospective legislation on our part, it offers at least many useful suggestions.

Ireland is divided, for poor-law purposes, into one hundred and sixty-three Poor-Law Unions. It is further subdivided into between three and four thousand electoral divisions, each division electing from one to four poor-law guardians to represent it at the Board of the Union. The tax-payers of each division support their own poor. The medical charities form part of its poor-law system of relief, and in the one hundred and sixty-three poor-law unions there are over a thousand dispensaries. There are over seven hundred dispensary districts, which are attended by a suitable number of physicians, apothecaries, and midwives. The elected guardians of the union have control of the whole, and have the power to nominate and appoint dispensary committees, which committees manage each institution. Medical attendance can be had at all hours, although many of the dispensaries in the rural districts are not opened oftener than one or two days in each week. The poor-law guardians appoint wardens in every dispensary district to distribute tickets. These officers are well-known gentlemen, and are accessible at all times. The ticket system is carried out to perfection. A white ticket entitles the holder to attendance at the dispensary, while a red one entitles him to attendance at his house.

Each poor-law union has a public hospital, to which all suitable cases are sent by the dispensary physicians. There is no part of Ireland, in fact, which cannot receive immediate aid for its sick poor. In the most remote districts no person is more than six miles from

any public dispensary. The medical officers of the rural charities are salaried, receiving from \$300 to \$750 per annum. The taxes for the support of this system are levied on the annual rental value of property, and the rate is in proportion to the number of paupers to be maintained. Vast as is the system, and large as is the number of sick attended, the expense is comparatively trifling. According to the last returns, relief was afforded to 837,669 persons for the sum of \$585,194. This sum includes all possible expenditures for rental of buildings, salaries, medicines, food, fuel, etc.

In almost every particular the system of poor relief in Ireland commends itself for our imitation.

Reviews and Notices of Books.

A PRACTICAL TREATISE ON THE MEDICAL AND SURGICAL USES OF ELECTRICITY. Including Localized and General Faradization; Localized and Central Galvanization; Electrolysis and Galvano-Cautery. By GEO. M. BEARD, A.M., M.D., and A. D. ROCKWELL, A.M., M.D. New York: William Wood & Co. Second Edition.

AFTER a careful perusal of this work of 794 pages, including nearly 200 excellent illustrations, which reflect great credit on the publishers and editors, and after a close analysis of 250 cases treated, we are fatigued but not convinced.

In the first place, the word electro-therapist occurs too frequently. We have for some time past decided to give up the use of this term, for the following reasons: it sounds too much like hydro-therapist, and one is as good as the other; we cannot classify an electro-therapist or say where he belongs; there is some danger of its becoming an epithet of reproach, a wish to avoid which is natural; in short, a regular physician can study electro-therapeutics, but he cannot be an alcohol, balneo, or electro-therapist. The distinction seems sufficiently clear, and we have been unable to find any such expression in the works of Remak, Althaus, Ziemssen, Rosenthal, and Onimus and Legros. It is used once or twice by Benedikt and often by Cyon, but by the latter in no terms of praise. We would suggest "medical galvanists," the term employed by Althaus, as a better name for those who treat disease solely by electricity. This point we dwell upon because it seems to us important, and is evidently so regarded by the authors of the work before us, for on pages 250 and 251 we read, "Any idiot or mere infant can hold two sponges on the body while the current is passing, and if that were all of electricity in medicine, writers on this subject would be needless. A dose of quinine or opium any fool can give or take, but to know when to give these drugs, how to give, and when not to give, requires oftentimes the best skill and experience. Similarly with electricity." Electro-therapeutics is not a science, and while we admit that an infant cannot treat disease by electrical applications, we hold most emphatically that any wise physician ought to be thoroughly competent to do so, and that most of such are competent. A feature of this work therefore—and so important does it seem to us in its relations to the medical ethics of specialists, that we leave little space for the consideration of others good or bad—is the apparent desire on the part of its authors to show that electro-therapeutics is a

science which has made great progress since Remak's time, and that long and patient study is required before its details are mastered. Whereas the truth of the matter is, that no great progress has been made, and that any sensible doctor of medicine can fit himself in a month's time, at most, to make all the applications as well as the so-called masters, and then proceed to build up a therapeutics of his own. Exclusive of those recorded under electro-surgery, notes are given of 223 cases. Out of these 29 are of hysteria and allied affections, and in all but two, general faradization and central galvanization were the remedies. The results, in general, were favorable, but there is certainly no science here, for hysteria interposes too many sources of error. In the cases given of cerebral and spinal congestion we have but to doubt the diagnosis, and in most of the cases of various affections which follow, although the cures are sometimes remarkably brilliant, there seems to be little evidence of any special skill displayed in their treatment. To convince the reader that there is a real call for the above criticism, we refer him to chapters 1 to 3, inclusive, of the part devoted to electro-therapeutics. Such claims cannot be passed over in silence.

Electro-physiology is admirably well treated of, and we can especially commend chapter 7, on Ohm's law. One hundred and eleven pages are devoted to electro-physiology. The authors appear to endorse Prof. Trowbridge's views against those of Du Bois-Reymond, on the so-called animal currents. The question is by no means settled, and as no attempt has been made to connect animal electricity with therapeutics, the pertinency of the discussion hardly appears, unless it be offered as an excuse to the reader for the remarkable statement on page 100, and to which we strongly object, as being by no interpretation true: "Electro-physiology cannot become a reliable basis for electro-therapeutics." We deny this in the name and in the interests of scientific medicine. Therapeutics is an art. Physiology is a science; and aided by chemistry and physics, has always been, and will ever remain the only reliable foundation for all therapeutics. We can do no better than to quote here an extract from a review of recent works on medical electricity (*Chicago Journal of Nervous and Mental Disease*, vol. I, No. 2, p. 209): "Still the practice of electro-therapeutics is yet largely empirical; and the amount of professional ignorance on the subject, even among otherwise well-informed practitioners, is something astonishing. And not only this, but this empiricism is even commended as the only true route of progress in this direction; and a distinguished authority has recently advised that the practitioner should make no attempt to master the principles of electro-physiology, and has expressed the opinion that practical electro-therapy is independent of, and in advance of physiology. We always regret such utterances on the part of educated physicians. They are too much like the cant of narrow men, who would deny the value of the very labors the results of which they utilize, and without which any other than the merest hap-hazard progress is impossible."

SPINAL PARALYSIS OF THE ADULT; ACUTE, SUBACUTE, AND CHRONIC. (INFLAMMATION OF THE MOTOR TRACT OF THE SPINAL CORD.) By E. C. SEGUX, M.D., Clinical Professor of Diseases of the Mind and Nervous System at the College of Physicians and Surgeons, New York. Read before the Academy of Medicine, and reprinted from its Transactions.

DR. SEGUX has made a contribution to medical literature, the value of which we hope will be appreciated. His cases have been reported with characteristic min-

uteness, in striking contrast with too many which may be found in similar works. The author admits (page 35) that "the elements for discussing the problem (as to whether the lesion be inflammatory or degenerative) are not yet in our hands," and it seems therefore somewhat premature that he should introduce a new name based on an apparent assumption that the problem is solved. "Spinal Paralysis of Adults" seems to us a preferable expression to the one suggested, until we obtain more light on the pathogeny of nerve-cell degeneration. We are glad to endorse what has been so ably presented under the heads of semiology and diagnosis, and are sure that a real service has been rendered by thus indicating the features which distinguish this from other affections and especially progressive muscular atrophy.

THE DISEASES OF THE STOMACH. The third edition of the "Diagnosis and Treatment of the Varieties of Dyspepsia." Revised and Enlarged. By WILSON FOX, M.D., F.R.C.P., F.R.S. With Illustrations. Philadelphia: Henry C. Lea. 1875.

THE book contains in a condensed form many facts and doctrines which are of essential value to the general practitioner of medicine. It is in this that its chief value consists. For without doubt, unless we except some observations of the author, all the teachings contained in this volume may be found in other works. It is the delight of the general practitioner, however, to find condensed treatises upon medical subjects which will bring before him practical results, without being obliged to struggle through ponderous works that may have been written to substantiate the same. This little work will therefore still be read with interest.

The style of writing is clear and forcible, and although some doctrines are set forth which are still regarded as unsettled, they belong more to the special department of pathology and physiology than to the everyday management of a class of diseases which is extremely perplexing.

A PRACTICAL TREATISE ON THE DISEASES OF WOMEN. By T. GAILLARD THOMAS, M.D., Prof. of Obstetrics and Diseases of Women in the College of Physicians and Surgeons, New York, Surgeon to the New York State Woman's Hospital, etc. Fourth edition, thoroughly revised, with one hundred and ninety-one illustrations on wood. Published by Henry C. Lea, Philadelphia, 1874.

THE reputation of this book is already too well established to be affected by compliment or criticism. The exhaustion of three large editions within five years, a translation into German, and the prospect of speedy translations into French and Italian, are special compliments, however, that can safely be taken as evidence of the intrinsic value of the work.

It is entirely unnecessary to attempt an analysis of the contents of the book, for those who possess it are already aware of its excellence. The number of practitioners of medicine who do not possess it is so small that it is not worth while to consume time in a vain endeavor toward their enlightenment.

In the last edition we still have a volume valuable for the student, valuable for the practitioner, and valuable for the teacher. The style of composition is very good, yet might be improved in many instances. The teachings of the book are at variance with the teachings of many eminent men in this department, yet they are so plainly stated and so reasonably argued that they must carry conviction with them. Many additions have been made in the present edition, and it has apparently been the aim of the author to bring his work fully up to the present advanced state of gynecological science. In that effort he has well succeeded.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 24, 1875.

DR. F. DELAFIELD, President, in the Chair.

DR. WEIR presented a specimen of lumbar colotomy (vid. p. 209).

DR. KEYES exhibited a specimen of impacted urethral calculus which had been removed by a novel method (vid. p. 163).

PRECOCIOUS DEVELOPMENT.

DR. BLAKE presented the cranium of an infant, which illustrated some very remarkable facts in connection with precocious development. There was an ossification of the cranial bones, and of some of the sutures. The child was born at full term, and was as large as one four months old, and as far advanced in its general development. The following were the measurements in inches:—

Dimensions of the Head—Occipito-mental, $6\frac{1}{2}$; occipito-frontal, 6; perpendicular, 5; transverse, $4\frac{1}{2}$; temporal, $3\frac{1}{2}$; round head over ears and under chin, $14\frac{1}{2}$; over chin, 16. *Thigh*—Circumference, 7, and calf, $4\frac{1}{2}$. *Chest*—Circumference under axilla, $13\frac{1}{2}$; breadth of shoulders across back, 7. *Arm*, over biceps, $4\frac{1}{2}$; circumference of forearm, $4\frac{1}{2}$; length to point of shoulders, $8\frac{1}{2}$.

DR. PUTNAM-JACOBI remarked that the first child was more apt to be disproportionately large and well developed as compared with the succeeding ones. The fact was probably best explained by the sedentary habits of the prospective mother, this very inaction tending to concentrate so much physical force towards the development of the fetus in utero.

DR. BLAKE stated that this was precisely the condition of his patient, she having been directed to lead a sedentary life in the fear of a miscarriage.

DR. HEITZMANN presented a specimen of catarrhal pneumonia removed from an infant who died while under the care of Dr. Lewis Smith; and detailed the microscopical appearances of the pleural epithelium when stained with solutions of nitrate of silver and chloride of gold.

COMPOUND FRACTURE OF PATELLA FROM MUSCULAR VIOLENCE.

DR. MASON presented a specimen of compound fracture of the patella, removed by amputation from a man aged twenty-five years. This patient had fractured his right patella by muscular violence, December 26th, 1873, was treated for the same in Bellevue Hospital, by plaster-of-Paris dressing, and was discharged the 15th of April following, with a stiff knee. On the evening of the 2d of January, 1875, he fell in the street, flexed the injured leg very strongly under him, separated the ligamentous band of union of the patella, tore through the tendon of the quadriceps, and besides cut the skin overlying the condyles to the extent of ten inches. At the time of the accident, the patient could place the forefinger between the two fragments, and he could flex the knee three inches. The wound was dressed with carbolized oil, and the limb placed upon a splint. Notwithstanding every care, the joint became disorganized, necessitating amputation at the middle and lower thirds of the thigh, which operation was performed January 25th. Dr. M. having a case of pyæmia in an adjacent ward, took

particular pains to guard the patient against infection, but seemingly to no purpose, as death from that disease occurred on the tenth day after the operation. The specimen was of interest as an example of compound fracture of the patella, the result of muscular violence.

PARTIAL STRICTURE OF INTESTINE—PURULENT INFILTRATION OF RECTAL WALLS.

DR. DELAFIELD exhibited specimens removed from the body of a patient of Bellevue Hospital, who, three months before admission, sustained a severe injury of his shoulder by a fall. He, however, was able to continue his work as a laborer until three weeks before seeking hospital relief. He then felt that he was losing the use of his legs, and within a few days he had complete paraplegia. When he was brought into the hospital the power of motion in both legs was lost, but there was still some sensation left. It was found, on examining the spine, that over the seventh dorsal vertebra there was an angular curvature outwards, and it was supposed that either a fracture had occurred, or that caries existed at that point. Three days before his death he was suddenly seized with incessant vomiting, and at the same time his abdomen began to swell. Before this he had suffered from constipation, but this condition was not difficult to relieve by the usual purgatives and enemata. The swelling of the abdomen was tympanitic in character, and this, with the vomiting, continued to increase until death. At the autopsy the seventh dorsal vertebra was found almost destroyed, its body being converted into a cheesy mass, presenting the ordinary appearance of caries of the spine. In consequence of the destruction of this body, the spinal cord was bent and compressed. The points of greater interest were found in the abdominal cavity. The small intestine, from the lower part of the ileum to the duodenum, was very much dilated, and was coated by recent fibrine. On following down the small intestine, it was found that in the lower part of the ileum there were two points of obstruction, due to the coiling of the gut upon itself, the result of old peritonitis. In the lower part of the colon, just above the sigmoid flexure, there was another small obstruction, produced in the same way. None of these obstructions were complete. On following down the large intestine to the rectum, the entire extent of the latter was infiltrated with pus, this pus being situated between the peritoneal and mucous coats. There was some slight purulent infiltration of the surrounding tissue. The patient's history did not throw any light on these conditions, neither did they seem to have given him any special trouble. The noteworthy point was the purulent infiltration of the walls of the rectum, without any coexistent disease of the mucous membrane, and apparently not caused by anything existing in the pelvic cavity.

The Society then went into executive session.

DR. JOSHUA RILEY, of Georgetown, Md., died recently of angina pectoris, aged 75 years. He graduated at the University of Maryland in 1824, soon after which he commenced the practice of medicine, and located in Georgetown. From 1844 to 1859 he occupied the chair of Materia Medica in the Medical Department of Columbian College, and for many years was President of the Medical Association of the District of Columbia. At the recent meeting of this society appropriate resolutions were passed, and remarks were made by Drs. Grafton Tyler, L. Mackall, jr., Armistead Peter, Noble Young, J. F. May and Leibermann.

Correspondence.

THE HYPODERMIC INJECTION OF QUININE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—If you deem the enclosed letter of sufficient importance, will you please give it a corner in your valuable journal. It is of importance from the minuteness of the dose employed; nine grains in two weeks for inveterate cases. This is the average success in seven cases. In the beginning of the epidemic of malarious fever, which has prevailed in this locality for the past few years, as well as in your city, and through the Eastern States generally, wherever the unprecedented drought has obtained, I found these, and occasionally even smaller doses, effectual, and sometimes one single dose, though the patients remained in the same locality; but as the epidemic has dragged on, and the vitality of the people has, I presume, become impaired by its repeated attacks, larger and larger doses, by hypodermic use as well as by the mouth, have become requisite. But owing to the more frequent occurrence of gastric irritability from the same cause, the not unfrequent absolute necessity for a resort to the former method has presented itself. In estimating the value of Dr. Miller's report, we must not forget that his patients had removed to a more healthy neighborhood.

In ordinary seasons of malaria, and in ordinary or sporadic attacks, I am confident that these, and even smaller doses, would be generally successful.

Yours truly,

FRED. D. LENTE.

The following is the letter to which reference has been made:

MOBERLY, MISSOURI, March 2, 1875.

DR. F. LENTE.—DEAR SIR:—During the month of February, 1873, several families came to this place from a section of country in an adjoining county known as the Three Forks of Chariton river, and notorious for its excessive malarial influences. Almost all of them had been suffering from chills for the past eighteen months. I will detail to you the history of one case, which will be a proximate average of the remaining seven.

On the 3d of March, 1873, H. A. presented himself at my office, his entire appearance indicating a high degree of malarial toxæmia. He remarked that he had been "chilling" for the past eighteen months, and had taken a great deal of quinine, and inquired if I thought I could cure him without giving him any quinine. Anxious to try the hypodermic treatment by quinine, according to the formula which you had the kindness to send me, I remarked to him that I thought I could cure him without giving him anything, and would only insert a little medicine in his arm. I inserted *three grains*, about half a drachm, of your solution, and he went off with his team, hauling dirt on the M. K. & T. R. R. On the Saturday following he returned to my office, looking better; no chill, and much elated at the success of the novel little operation for curing the chills. I then made another insertion, and a week after a third insertion, of three grains each. Had no chills after the first insertion, although he was exposed to all the variable weather incident to the month of March in this latitude. I saw him occasion-

ally during April and May, but no return of chills. Since then I never treat chronic chills in any other way, and I feel much indebted to you.

Yours truly,

J. H. MILLER, M.D.

THE VALUE OF SPECTRAL ANALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

MY DEAR SIR:—When I wrote my reply to Dr. H. G. Piffard, in THE MEDICAL RECORD, January 30, 1875, answering all questions in conformity with strict scientific rules, I expected that this would end the controversy. But Dr. P. having sought the aid of Dr. Draper in attempting to confute some of my statements, I am compelled again to defend my position.

In looking carefully over Dr. Draper's letter, I am pleased to find that it contains not one word calculated to weaken any of the points originally advanced by me in the lecture before the Medico-Legal Society. On the contrary, I observe in it a masterly protest against Dr. Piffard's peculiar manner of criticism. ;

In answer to an inquiry, whether his map contains any sunlines at the red end of the spectrum, Dr. Draper says: that said map does not contain any such lines at that part of the spectrum; that he has photographed lines from H to O at the ultra violet portion of the spectrum, but has since succeeded in photographing the ultra red rays also, but these latter photographs he has not yet published.

In THE RECORD of Oct. 15, 1874, will be found all that I have said upon this subject. It contains two distinct propositions, and reads thus:

1. "Professor Draper of this city, whose merits in this direction are gratefully acknowledged, has given us a map containing a great number of sunlines, invisible under ordinary circumstances, but which can be made visible under certain favorable conditions.

2. "These additional lines are made *evident* (not evidently as Dr. P. has it) at both the red and violet part of the spectrum, making it of course longer than usual."

And now can any one point out to me the word or sentence in the foregoing quotation, in which I asserted that Dr. Draper has photographed lines at the ultra red part of the spectrum!

That Dr. H. Draper has given us a map containing a great number of sunlines invisible under ordinary circumstances, is a fact gratefully acknowledged all the world over; and although not personally known to Dr. Draper, I was pleased to call up his rare merits in this connection as a meritorious American investigator. But Dr. Draper's map was not the only one known to me, when I wrote my lecture "On the Importance of the Spectroscope in Forensic Cases." I had also before me the beautiful map of Stokes, resulting from his researches on fluorescence, and published in Roscoe's work on Spectrum Analysis, 2d edition, p. 205. Said map gives the ultra violet rays as far as N.

That, secondly, these additional lines (invisible under ordinary circumstances) are made evident at both the red and violet part of the spectrum, is a well-known fact, which Dr. Piffard will probably not undertake to controvert. It is certainly gratifying to learn that Dr. Draper has succeeded in photographing the lines of the visible spectrum from b downward, and that the picture comprises not only the regions including E, D, C, B a, and A, but also the ultra red rays. (Draper's letter, Feb. 20, p. 133.)

Independent of this statement of Dr. Draper, Roscoe makes mention of these invisible heating or red rays (see p. 205), and in Schellen's work, p. 251, you will find

Brewster and Gladstone's map of the so-called atmospheric lines, giving lines in the ultra red marked Y, Z.

My original statement needs therefore no modification whatever.

I will now show that Dr. Piffard has receded from his original position. In his first communication (MEDICAL RECORD, Nov. 16, p. 605), he says:—"A similar error is committed in reference to Dr. Draper who (quoting from my lecture), has given us a map containing a great number of sunlines invisible under ordinary circumstances; these additional lines are made *evident* ("not evidently!!!") at both the red and violet part of the spectrum." "The fact is," Dr. P. continues, "Dr. Draper's photograph shows no lines in red, orange, yellow, or green, for reasons known to every photographer and physicist." (I italicize the sentence.) Now, mark Dr. Piffard's discomfiture. Dr. Draper says in his letter, "I have since succeeded in photographing the lines of the visible spectrum, from b downwards, and the picture comprises not only the regions including E, D, C a, and A, but also the ultra red rays!"

The reader will remember that these lines occupy the red, orange, yellow, and green regions of the spectrum.

It is interesting to observe how this plain statement of Dr. Draper demolishes Dr. Piffard's theory, "that no lines in red, orange, yellow, or green can be photographed, for reasons known to every photographer and physicist."

It is amusing in this connection, and in the face of the facts above stated, to refer to Dr. Piffard's sinister insinuation that I did not know when looking at Dr. Draper's map which end of the spectrum was represented.

Dr. Piffard states that I misquote him in paragraph nine of my reply. As I have not numbered my paragraphs, I presume he has reference to his luminiferous ether light and heat theory. I most positively deny the charge. I have quoted him verbatim, with the exception of his uncalled for remarks.

I come now to the question whether my view is correct or not, that the hæmatocryst, of the blood possesses great stability, that it will retain its characteristic optical relation for years, and that no putrefactive process can annihilate its integrity. Dr. P. has a perfect right to differ, and, if he can, let him prove the opposite view he holds, that hæmatocryst. (not the artificial crystals) is so unstable that even common atmospheric influences will affect its integrity.

Dr. Piffard has quoted a few authorities, firstly "Foumouze," a French scientist, who says: "Hæmatocryst. is characterized *chemically* (chemiquement) by its extreme unstability."

The fact that hæmatocrystalline is readily altered by chemical means is distinctly, clearly, and freely set forth in that very lecture before the Medico-Legal Society, October 15, see p. 532, second column. Let us quote a few lines: "When blood or hæmatocrystalline solution is acted upon by any acid, except prussic acid, or by some alkali, chloroform, and some other agents, it is split up, or *chemolized*, as we term it, into albuminous substances, and a coloring matter, which contains all the iron that is contained in the blood, but none of the sulphur of the original compound." I have also given a diagram or map of quite a number of spectra corresponding to the various *chemical* changes of the blood. Foumouze, therefore, does not help the Doctor. He quotes also Dr. W. Preyer, in the German language. This quotation may look formidable to those who do not understand the German language, and so I will translate it for their benefit. "Very peculiar are the changes of the hæmatocrystalline *spec-*

trum whenever a decomposition of the solution takes place. If the pure solution is allowed to stand several hours at the temperature of the room, the color grows darker," and so forth.

Dr. Preyer speaks here of solutions of artificial hæmatocrystalline, and not of blood-solutions. The whole of Chapter VI. treats of these artificial crystals, of their pellucidity, their power to refract light, their lustre, their color, and their spectrum. These artificial crystals are entirely foreign to our polemic, and can be introduced by the critic with no other result than to befog the question at issue. Consequently the "German quotation will not help him."

Dr. P. quotes from my "Archiv" paper, in which I spoke of a band in red, which we find in old blood, and which was thought by Hoppe Seyler to belong to a substance named methæmoglobin. But in said paper I showed also that this substance has never been demonstrated, *i. e.*, obtained, and that it is hypothetical entirely. The spontaneous transmutation spoken of by Hoppe Seyler results, as Kuehne has lucidly shown, from the chemical action of butyric and formic acids, which are generated in small quantities during the decomposition of blood. (Archiv, No. 5, p. 455.) Preyer says: "Die Blutcrystalle," p. 196. "The term methæmoglobin may be considered a superfluous designation," and Hoppe Seyler himself has materially modified his hypothesis. (See Medicinische Chemische Untersuchungen, Berlin, 1871, p. 378.)

The intelligent reader will concede that this is very weak argument against the positive results of intelligent experiments, and against the direct and positive authorities quoted in my first reply (see p. 85). These experiments show that after years of exposure in the dry state, as solution in air-tight vessels, as well as in vessels to which the air had access, the characteristic bands of hæmatocryst. could be produced in all their former integrity; that from them we could produce Stoke's reduction band, and by shaking up with air reproduce the two bands between D and E.

There is no doubt a part of the hæmatocryst. is used up by the chemical action of butyric and formic acids as Kuehne has shown; another quantity may be chemolized by sulphuretted hydrogen and other gases of putrefaction; but when these chemical agents are no longer active, the remaining hæmatocrystalline *knows no spontaneous decomposition*, it remains intact for years, and will reveal its presence spectroscopically by giving the characteristic bands between D and E with great intensity. It may do Dr. P. no harm to acknowledge that the argument is unanswerable.

In Dr. P.'s first communication, Nov. 16, p. 605, he said, "That crystals of hæmatocrystalline can only be obtained from fresh, and not from dried blood." I asked him, in my reply, to point out any authority, or whether he had made the necessary experiments to justify him in saying that it cannot thus be obtained. To this he answers (RECORD, Feb. 20, p. 134), "Dr. Waterman intimates that I denied the production of any (sic) crystals from old blood. I have frequently obtained crystals of hæmin from old dried blood." Dr. P., I am sorry to say, evades the question; he positively asserted that crystals of hæmatocrystalline cannot be obtained from old dried blood. *That is what I challenged him to prove.* He says hæmatin has never been crystallized, and quotes Preyer. On page 5, "die Blutcrystalle," Preyer speaks distinctly of "Lehman's hæmatin im crystallisirten Zustande;" "Lehman's Hæmatin im crystallisirten Zustande;" and in Otto Funk's "Atlas der physiologischen Chemie," Tafel IX., Dr. Piffard may find a beautiful colored plate, representing the crystallized hæmatin as described by

Lehman. On this question I am uncommitted. But when Dr. P. says I made an incorrect quotation from Mr. Preyer, I must deny the charge.

I claim my quotation is exact, true, and *not* incorrect. Here it is, p. 5.

"Blutcrystalle hingegen heissen auch das Teichman'sche Hæmin und das damit identische Lehman'sche Hæmatin im crystallisirten Zustande."

Blood-crystals we call also Teichman Hæmin, and Lehman's hæmatin in crystallized condition, identical with it. Preyer closes the chapter by saying: Diese farbigen Körper sind jedoch sämtlich Zersetzungsproducte der Hæmoglobine für welche der Ausdruck *Blutcrystalle* schlechtweg vorbehalten bleibt.

"These colored bodies are, all of them, products of decomposition of the hæmoglobins, for which the term *Blood-crystals* is retained under all circumstances (schlechtweg is untranslatable)." In closing up I remind Dr. P. that Teichman himself, according to Virchow (see Cellular Pathology, p. 178), has quite recently begun to entertain doubts as to whether his hæmin is not really a sort of hæmatine, and that *the same Virchow* speaks of my labors "as a concise and pretty perfect review of the results of spectral analysis in physiology and pathology." (Jahresbericht über die Leistungen der gesammten Medizin, Berlin, 1871, p. 195, edited by Drs. Rudolph, Virchow, and Hirsch.

In conclusion, when Dr. Piffard says "That Dr. Waterman had not at any previous point in his lecture made mention of other crystals than those of hæmatocryst," he ignores the great and towering fact, that ample consideration was given to these other crystals in a subsequent part of the same lecture, p. 532, to hæmatine and cruentine under all their chemical changes, and a plain and distinct statement was made, that through them detection of crime was possible, spectroscopically, when all other means failed, p. 533. There is no loophole here, and Dr. Piffard's critique, resting upon such treacherous bottom, is destined to crumble and disappear from the sight of scientific men.

Very respectfully,

S. WATERMAN, M.D.

BOIL PEST IN TRIPOLI.—During the early part of last year a rare and malignant disease made its appearance in Tripoli, characterized by the formation of two or three boils in the axilla, or upon the arms, legs, or abdomen. Of ten instances of the affection, observed by Dr. Reval, seven terminated fatally within twenty-four hours. It was regarded as a significant feature that the disorder was limited to the tribe of Merdji, the inhabitants of the surrounding districts enjoying an immunity from the malady, although they maintained uninterrupted communication with this tribe. The authorities at Constantinople appointed a commission to inquire into the causes of this epidemic, and this commission, of which the American Consul, Mr. Temen, was president, have recently made an exhaustive report. In accordance with this report the epidemic in question had its origin in miasmata proceeding from a burial-ground in Merdji, where it is the custom to inter the dead in shallow graves scooped out of the sand, the corpse being simply covered with straw. When it rains these graves are filled with water, which, upon the following day, is rapidly evaporated by the hot sun, and this contributes to the rapid decomposition of the bodies, by means of which the surrounding atmosphere is loaded with the putrid emanations. In winter the graveyard is converted into a small lake, the water from which is used for drinking purposes.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 7th to March 13th, 1875.

O'REILLY, R. M., Ass't Surgeon.—Granted leave of absence for twenty days. S. O. 28, Dept. of the Platte, March 5, 1875.

MUNN, C. E., Ass't Surgeon.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and upon its completion return to his proper station. S. O. 39, A. G. O., March 8, 1875.

Medical Items and News.

N. Y. ACADEMY OF MEDICINE—DR. DELAFIELD.—At a stated meeting, held on the 4th inst., the following resolutions were unanimously adopted:

Whereas, On the 13th of February, 1875, Edward Delafield, M.D., an original Fellow of this Academy, departed this life, at the advanced age of 81 years; therefore,

Resolved, That the Academy would put on record its high appreciation of the great services rendered by him to the Medical Profession during his long career, by his wise councils, his successful discharge of many important trusts committed to him, and above all, by the consistent example of his daily life, his career as a teacher, his wise administration of the affairs of a great educational institution, and his regard for the suffering, as evinced by his establishment of the "Society for the Relief of Widows and Orphans of Medical Men," and as chief executive officer of the "Roosevelt Hospital," all bear witness to his high intelligence no less than to the benevolence of his heart; while his honorable conduct, his humane and sympathetic deportment, ennobled the profession of which he was so honored a member. He has thus left us an example worthy of all imitation.

Resolved, That these proceedings, duly certified, be communicated to the family of the deceased, and that they be published in THE MEDICAL RECORD and N. Y. *Journal of Medicine*.

Signed,

JOHN G. ADAMS, M.D.,	} <i>Committee.</i>
WILLARD PARKER, M.D.,	
THOMAS M. MARKOE, M.D.,	

March 4th, 1875.

ANOTHER CHANGE IN THE MEDICAL BOARD OF BELLEVUE HOSPITAL.—On the 11th inst. the Board of Commissioners of Charities and Correction restored to the Medical Board of Bellevue Hospital the physicians and surgeons who lost their positions by the action of the former Board of Commissioners, in the summer of 1874. The following resolutions were adopted:

Resolved, That the Medical Board of Bellevue Hospital shall on the 15th day of March, 1875, be organized in the manner following, and thereafter the Board, as at present constituted, shall cease to exist.

Second. That the Medical Board be increased to twenty-four members.

Third. That on the 15th day of March, 1875, the following named physicians and surgeons shall constitute the Medical Board of Bellevue Hospital: Drs. Alonzo Clark, James R. Wood, John J. Crane, Isaac E. Taylor, Austin Flint, Fordyce Barker, Alfred L. Loomis, Thomas M. Markoe, Lewis A. Sayre, William T. Lusk, Stephen Smith, Alexander B. Mott, Henry B. Sands, John W. S. Gouley, Frank H. Hamilton, Edward G. Janeway, Francis Delafield, William H.

Thompson, Charles A. Budd, Gouverneur M. Smith, Erskine Mason, William M. Polk, Ernest Krackowizer and Abraham Jacobi.

Fourth. That there be a department for the diseases of women.

Fifth. That there be a department of orthopædic surgery and diseases of children.

Sixth. The Board to be divided as follows: Ten physicians, two of whom, hereinafter named, to be appointed to the department of diseases of women, and ten surgeons; also two for orthopædic surgery and diseases of children, and two for the department of maternity.

Seventh. The Medical Board shall be divided as follows: Physicians—Drs. Alonzo Clark, Alfred L. Loomis, Austin Flint, Edward G. Janeway, William M. Polk, Abraham Jacobi, William T. Lusk, Charles A. Budd, Francis Delafield, William H. Thompson. Surgeons—Drs. James R. Wood, John J. Crane, Stephen Smith, John W. S. Gouley, Frank H. Hamilton, Alexander B. Mott, Henry B. Sands, Thomas M. Markoe, Ernest Krackowizer, Erskine Mason.

Department of Diseases of Women: Dr. William T. Lusk, Dr. Charles A. Budd. Department of Orthopædic Surgery and Diseases of Children: Dr. Lewis A. Sayre, Dr. Gouverneur M. Smith. Obstretical Department of Maternity: Dr. Isaac E. Taylor, Dr. Fordyce Barker.

Eighth. That the Medical Board nominate to the Commissioners of Public Charities and Correction physicians and surgeons to fill vacancies.

Ninth. That the resolution passed November 23, 1866, limiting the term of service of the Medical Board to fifteen years be and hereby is reseeded.

Tenth. That the resolution passed July 28, 1874, making the service of members of the Board continuous through the year be and is hereby reseeded.

Eleventh. That the attending physician and surgeons shall serve twice each year, and each service shall continue for two months.

Twelfth. That the Medical Board shall, at their first meeting, divide themselves into three classes—eight members to serve three years, eight members to serve five years, and eight members to serve seven years—the classification to be determined by lot.

Thirteenth. That the rules and regulations of the hospital not inconsistent with the foregoing be continued in force.

COLLECTING ASSOCIATION.—The physicians of Jackson County, Michigan, have associated themselves together in an organization, to be known as the "Jackson City and County Physicians' Collecting Association," and have adopted the following preamble and articles of agreement:

Art. 1st. We will, at the expiration of every month, deliver all our unsettled accounts into the hands of such persons as we shall hereafter appoint (one or more in each town), and authorize said persons to collect and settle the same.

Art. 2d. We will require our collectors to report to the association the names of all persons who refuse to pay or settle their accounts satisfactorily.

Art. 3d. The names of all such persons shall be furnished to every member of the association, and every member shall be prohibited from rendering them professional services, until they shall have satisfactorily settled all past accounts.

Art. 4th. The collectors may, upon instructions from any member of the association, remit a portion or all of his claim against those who, while willing, are too poor to make payment in full.

Art. 5th. This association shall require the persons

employed as collectors to furnish sufficient bonds for the honest discharge of their duties, and to report weekly to all who have accounts in their hands.

THE NINETY-SECOND ANNUAL CATALOGUE OF THE HARVARD MEDICAL SCHOOL shows very gratifying results from the change in the system of teaching. The number of students appear to be steadily increasing, and the classes now number as follows: Graduates, 6; third class, 29; second class, 52; first class, 108. As an example of the favor with which the school is considered by its students, it may be mentioned that the names of but four members of the second class of last year fail to appear in the third class of the present year. The degree of preliminary education attained by the scholars is shown by the fact that eighty of the 192 had received college degrees. A recapitulation by States shows that by far the majority of the students are Massachusetts men, viz., 134, and of these seventy-two are from Boston and Cambridge. Only three are from New York State—two from Brooklyn and one from Geneva. Other States and countries are represented in the following proportions:

Maine, 8; New Hampshire, 6; Vermont, 2; Rhode Island, 10; Connecticut, 4; New Jersey, 1; Maryland, 1; Pennsylvania, 3; Ohio, 2; Illinois, 1; Minnesota, 1; New Brunswick, 4; Nova Scotia, 6; Cuba, 1; Barbadoes, 1; Brazil, 1; Buenos Ayres, 1; and Japan, 1.

SMALL-POX AND VACCINATION IN CHINA.—The late emperor of China died, it is stated, after eleven days' illness, from an attack of small-pox, which disease is very prevalent in Peking. The help of foreign medical men had been persistently refused, and the emperor was attended only by his chief physician, Nona Tzen.

Galignani, speaking of the death of the emperor says that it might be inferred that vaccination is not practised in the Celestial Empire. This, however, is not the case. The virtues of the cow-pox were known to them many years before Jenner discovered it in our part of the world. Their historians fix it at about the twelfth century of our era. Now, as we got the small-pox from the Arabs toward the end of the tenth century, when Rhazes first described it, the question arises as to whether that disease existed in China before. A physician of that country, who has written an extensive work on medicine, says on this subject that small-pox was unknown until the middle of the reign of the Cheou dynasty, which flourished about the sixth century before Christ, and that it was only toward the end of the Song dynasty, answering to our twelfth century, that inoculation was practised on young children as a means of protection from the spontaneous malady. The experiment was first tried on the Emperor's grandson, and succeeded perfectly, and for more than fifty years the reputation of this treatment grew in the minds of the people, but it became gradually apparent that the remedy was not infallible, especially when the disease assumed an epidemic character. As for the cow-pox, the missionaries at Peking sent over accounts of it as early as 1779, while Jenner only published his discovery in 1799. The way in which the Chinese inoculate the cow-pox is this: the dry virus, in a pulverulent state, is blown through a silver tube into the left nostril, if the patient be a girl, and into the right one in the case of a boy. A second and more modern method consists in dissolving the dry virus in four or five drops of clear water; this is then taken up in a little cotton which they thrust into the right or left nostril, according to the sex, as above stated. The third way consists in performing the same operation with fresh virus, which is taken on the spot from a healthy child.

SCHOOL FOR IDIOTS.—The Legislature of Illinois has appropriated \$185,000 towards a school for feeble-minded children, to be located either in Jacksonville or Quincy.

A MEDICAL COLLEGE IN ASIATIC TURKEY.—Rev. T. C. Trowbridge, formerly of Michigan, and now a missionary in Turkey, purposes establishing a College at Aintab, a city some sixty miles north-east from the Mediterranean Sea, the most important feature of which is to be a medical school.

THE RUSH MEDICAL COLLEGE at its last commencement graduated seventy-three students.

THE DISTURBANCES IN THE EUROPEAN MEDICAL SCHOOLS seem to have reached their height in Barcelona, Spain, where the professor of physiology, Dr. Varela, was so interrupted and insulted during his lecture that he drew a revolver and threatened the disturbers. The most intense excitement followed, and it was necessary to call in the aid of the police to enable the professor to escape the fury of the students.

A SCHOOL OF DENTISTRY has just been established in Vienna.

M. PAJOT, the well-known Professor of Obstetrics of the Faculty of Medicine of Paris, having expressed his intention to retire from the faculty, a petition signed by six hundred and sixty-three students, including a considerable number of *internes* of the hospitals, was addressed to him asking that he might reconsider his determination and continue his course. The desire has been so unanimous that M. Pajot has consented.

THERE is no necessity for a Prison Reform Association when a twenty-five cent box of salve is advertised as a complete cure for a felon.

EXAMINATION ON SANITATION.—The Senate of the University of London is contemplating the institution of a special examination in the subjects which relate to public health; a course which has been recommended by a vote of Convocation.

DR. HINGSTON, of Montreal, has been elected mayor of that city by over three thousand votes.

THERE is a Cyclops on exhibition in Paris—a man from Australia, with only one eye, and that in the middle of his forehead.

PRACTICAL FILTRATION OF AIR.—The air that is supplied to the Houses of Parliament passes through filters of cotton wool. After being used for a short time the filters become of a heavy, murky brown color, and thick with dust and organic impurities. The sieves through which the air is first passed have deposited near them a heap of intercepted particles.

THE GERMAN ASSOCIATION OF NATURALISTS AND PHYSICIANS will have their next meeting on the 18th of Sept., at Gratz, the capital of Styria.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, March 22.—Medical Society of the County of N. Y.

Tuesday, March 23.—American Microscopical Society; Yorkville Medical Association.

Wednesday, March 24.—N. Y. Pathological Society.

Thursday, March 25.—N. Y. Medico-Legal Society; Brooklyn Pathological Section; Jersey City Pathological Society.

Friday, March 26.—Medical Library and Journal Association, "Report on Obstetrics," by Dr. Matthew D. Mann.

Saturday, March 27.—N. Y. Medical and Surgical Society.

Original Communications.

INUNCTION.*

By W. R. FISHER, M.D.,

HOBOKEN, N. J.

THE use of oils and fats in medicine, either alone or in combination with other remedial agents, is of very ancient origin. The writings of the oldest medical authorities which have come down to us make reference to the practice of inunction, and not only was it in common use in Egypt, Greece, and Rome, but there is reason for believing that among many of the savage and semi-civilized tribes and nations it has been used for ages. The Greek and Roman physicians employed it as a means of treating disease, and it ultimately became a hygienic necessity among the people in the *régime* of the gymnasium and the gladiatorial contests, and as an important part of the bath.

At the present time, however, in Europe and America, inunction is confined within much stricter limits than was the case in times gone by. The oils and fats, when applied externally, are now used mainly as vehicles to convey a limited number of medicines to the skin or to the subjacent tissues, either as local remedies or to affect the system at large, and chiefly for the former purpose. Mercury, iodide of potassium, and iodine are the chief agents which are at present introduced into the system through the skin, by means of fatty matters, with the object of influencing nutritive changes in the economy, or, in other words, as alteratives. In the London *Lancet* for May 25, 1872, p. 709, Mr. John Marshall, F.R.S., recommends to the profession the use of solutions of oxide of mercury in oleic acid as topical applications for the treatment of all diseases in which this drug is indicated. In addition to the greater cleanliness of these preparations over the ordinary unguents, he claims that they "have a much greater diffusibility or penetrating power than the old mercurial ointments, for they are absorbed by the skin with remarkable facility, and manifest the remedial effects with great promptitude." Morphia, atropia, cantharidine, quinine, and croton oil have also been combined with oleic acid and introduced into the system through the skin with good effect. It is very probable that many other remedies will soon be added to the list. For the production of local effects upon the skin, or upon wounds or ulcers, we use unguents and cerates as astringents, sedatives, irritants, stimulants or parasitocides. So, too, belladonna, atropine, and aconite may be used by inunction to produce their specific effects upon the pupil of the eye, but in modern practice this method of application has given place to others, which are much cleaner, surer, and more easily regulated.

The uses of unguents and cerates, together with their composition and effects, are so well known and so fully described in our books that it is useless to enlarge upon them here. The purpose of this paper is to direct the attention of the Society to the use of the oils and fats in a manner quite different from that which has just been briefly referred to; to point out how these may be used in medicine without the admixture of other medicinal agents; to go back to the practice of antiquity and bring forward a good thing of the past which has been hurried over and well nigh forgotten

in the rapid march of progress. The neglect which has fallen upon the old method of inunction, which once constituted the main reliance of a school of physicians (the Iatralapeutics), is surprising in view of its great virtues as a means of treatment in a variety of diseases. Scarcely a reference to its use is to be found in the works of modern authors who treat of the *materia medica*. Our Dispensatory does not refer to it; Waring and Stillé say but little of it, and Sydney Ringer by no means gives it a sufficiently prominent mention.

The fats and oils play a very important part in the nutrition of the body and in the evolution of force for the exercise of function by the various organs and tissues. They are as essential to life as air or water. It is now held by many physiologists that it is the combustion of the fatty elements, and not that of the nitrogenous, which originates force in the human body; the nitrogenous substances holding a secondary position to change this force into its expression as nerve-force, muscle-force, liver-force, and the like. It therefore becomes a matter of great value to the physician to have as many ways as possible of introducing this element of food into the body, for although the stomach is the readiest recipient, yet sometimes it refuses to do its work, in spite of all the attempts of the apothecary to prepare the dose in an agreeable form; sometimes, too, the remedy, when given by the stomach, does not produce the effects which we may otherwise attain. In either event the skin offers us its immense surface as an absorbent, and we can there apply our oils and fats by inunction.

Inunction consists in smearing the surface of the body, either partially or entirely, with oil, lard, or suet. The oil may be either of vegetable or of animal origin, but the former is much to be preferred, because the decomposition which takes place upon the skin, when animal oils are used for a length of time, gives rise to such a stench that the patient becomes disgusting to himself and to every one around him. When cod-liver oil was introduced into practice, it was used by inunction to a considerable extent, but this was soon abandoned on account of its disagreeable odor. There is no reason why the animal oils and fats should be used externally. Their internal use is determined in great measure by the fact that they are more readily tolerated by the stomach than the oils of vegetable origin, and that consequently they can be given in larger quantities and for a longer time. The vegetable oils, however, are taken up quite as readily by the skin, and therefore they are to be preferred. It is true that they are not absolutely free from odor when thus employed, but there is not sufficient to render them seriously objectionable, and, when a patient has unusually acute olfactorys, the addition of a perfume will remove all difficulty on the score of smell. For general use pure olive oil is the best of the vegetable oils. It is comparatively cheap, it is readily absorbed by the skin, and it gives rise to very little unpleasant odor.

When a general inunction is to be made, it is advisable to precede it by a warm bath, whenever the condition of the patient will admit of this preliminary, for the action of the oleaginous material is decidedly promoted by it. After the bath the patient should be clothed in a loose flannel wrapper, which should be long enough to cover the feet, in order to protect the sheets. The oil, slightly warmed, should then be applied liberally over the whole body and limbs by means of the bare hand of an attendant. The first effect that is noticeable after such an application is a general sense of comfort on the part of the patient;

* Read before the District Medical Society for the County of Hudson, February 2d, 1875.

when nervous irritation is a symptom, it is observed to diminish to a greater or less extent. Soon a gentle perspiration shows itself upon the whole body, and sometimes a slight erythematous eruption is apparent for a short time. It is probable that the sedative effect upon the nervous system is due in great measure to the gentle friction of the skin, and not directly to the oil itself. The secondary effects of general inunction are shown by increased glandular action and by marked improvement in nutrition and growth, in cases which are suitable for its application. Before passing to the consideration of these secondary effects, it may be well to refer to the local effects and uses of inunction in *diseases of the skin*. Oil is applied locally to protect the skin from irritating discharges and acrid secretions. In scaly diseases, as psoriasis and xeroderma, it is used to soften the skin that is hardened by disease and liable to crack. In impetigo, eczema, and favus it is useful to soften the scabs and facilitate their removal. In ringworm of the scalp, oil affords a good protection to the unaffected hairs and prevents the spread of the disease. Inunction with lard has been used with success in scabies by Professor Bennet, and he goes so far as to claim that the usual treatment by sulphur ointment is efficacious solely on account of the oleaginous matter, and that the sulphur might as well be left out. In erysipelas Erasmus Wilson recommends inunction with lard in preference to all wet applications. He first relaxes the skin with steam or hot water, then saturates it with hot lard, and covers it entirely with wool.

It has been claimed, especially by some French writers, that olive oil, when applied locally and to the body generally, acts as a protection against the bites of venomous reptiles and insects, and some reports seem to support this view; but the number of observations has thus far been altogether too few to substantiate such a claim for its use.

Next in order come *fevers*,—a class of diseases in which inunction is used both for its local as well as its general effects. In the exanthematous fevers it is used to a considerable extent. Schneeman, of Hamburg, has the credit of reinstating this method of treatment, for his reports on the use of inunctions of lard in scarlet fever made the practice quite common at one time in Europe and in this country, so far as that disease was concerned. Mautner, of Vienna, preferred the use of suet in scarlet fever, and West, in his work on the diseases of children, says that he regards it as far more efficacious in relieving the burning heat of skin than sponging the surface of the body with tepid water. He does not think that it prevents desquamation nor the appearance of albuminous urine, but he regards it as lessening the amount of the former and as diminishing the risk of the latter assuming a serious character. Inunction also helps to limit contagion by preventing the poisonous scales, during the process of desquamation, from being carried about by the air. The applications in the exanthemata should be made twice or thrice daily. Olive oil can be substituted for the lard or suet, and, to my thinking, is to be preferred to either. In small-pox the application of oil has been recommended to prevent pitting. Whatever influence it may exert in this direction is probably due to the softening of the scabs, which the oil promotes, and in this way serves to prevent the continuance of the ulcerative process after the pustules rupture and dry down. When the scabs are allowed to become dry and hard, the destruction of the skin is much greater than when they are softened by external applications and are taken off. In the earlier stages of small-pox, inunction serves a useful purpose in

allaying the extreme itching and irritation of the skin, and in soothing the nervous irritability which is thus excited. In typhus and typhoid fevers inunction is of use as a means of introducing a form of nourishment into the body, which often, on account of the condition of the digestive apparatus, cannot be administered by the mouth.

Inman (*Restoration of Health*, 2d edit., p. 230) says that during epidemics of the plague in Eastern cities the dealers in oil were observed to escape the disease, and that this has led to the common practice there of using inunctions of oil as a prophylactic. In Malta, those who had the care of the sick and dead during an epidemic of the plague wore dresses which were saturated with a solution of wax and oil, leaving the face alone exposed, and all who were so protected escaped infection. On the other hand, Stillé (2d edit., vol. 2, p. 410) states that he has been able to find very little ground for this popular Eastern belief, and that he puts no faith in the use of oil as a prophylactic against the plague.

Diseases of the Alimentary Canal.—In all acute and chronic inflammatory diseases, as well as in the functional disorders of the stomach and bowels in children, the use of oil by inunction is of great value. As an instance of its striking effects in an extreme case of cholera infantum, resulting from improper feeding, I will cite the following case, which occurred in the practice of Dr. Lewis Fisher, of New York, about four years ago. The doctor was summoned to a town near New York to see a child of four months of age, who was reported to be in a dying condition. He was sent for more to satisfy the mind of its mother, who had formerly been a patient of his, than with any expectation on the part of the rest of the family that his visit could result in any benefit to the child. The physician who had had charge of the case—a gentleman of excellent standing and large practice—had given it up, after a careful and conscientious treatment *secundum artem*, telling the parents that nothing more could be done, and that death must follow in the course of a few hours. Doctor Fisher found the child in the condition of collapse which the last stage of cholera infantum presents. He could suggest nothing in the way of medication that had not already been tried without avail; but he had read, a short time before, a paper, in the London *Lancet*, by Dr. Knaggs, on "Anointing in Infantile Disorders," and, as a last resort, he resolved to try what oiling would do in this instance. He directed the mother to wrap the baby in flannel, and to oil it from head to foot with warm sweet oil every hour, and came away, expecting to hear on the next morning that the child was dead. But on the next morning the child was better. The oiling had been faithfully kept up, and the child had steadily improved. After each application it seemed to be more and more soothed and strengthened; the vomiting ceased, the passages from the bowels improved in color and consistency, and diminished in number. This child recovered entirely, and is now alive and well, owing its life, without doubt, to the use of oil by inunction; at least this is the opinion which Doctor Fisher and the parents of the child adhere to, but the family physician, with true conservatism, complacently took all the credit of the recovery to himself, and attributed the cure to the medicine which he had prescribed, and some of which, he claimed, was within the child's belly when the oiling was commenced. Such a happy result as this, of course, cannot be expected in extreme cases of this serious malady; but a single example may serve as an encouragement to us to try this simple remedy, even in cases which are

apparently hopeless. I have never seen a case of acute or chronic diarrhoea in children, in which inunction has been properly used (and I have prescribed it a considerable number of times in such instances), without more or less resulting benefit. Sometimes it is difficult to induce the parents to use the remedy, for it involves a good deal of trouble, and, being new to them, it does not always invite their confidence; sometimes, too, they will not use it according to directions, because they are afraid of annoying the little sufferer. But, when you can induce them to give it a fair trial, they will usually persist in the applications, for they soon see for themselves that the child is soothed by them, the evacuations are checked and modified, sleep is induced, and the general comfort of the patient is greatly promoted. Even in cases which have terminated fatally, I have more than once had parents express to me their thanks for suggesting this remedy, which has acted so decidedly to relieve the sufferings of their children.

A child was born in May of the past year in a weak and puny condition, after a prolonged labor, which required the aid of the forceps to complete it. The mother was extremely anxious to nurse her baby, and persisted in the attempt after it was plainly evident to those around her that she was quite inadequate to the task. Three weeks elapsed before she consented to have a wet nurse for her child. By this time he was so feeble that she was seriously alarmed for his life. A wet nurse was immediately procured, and then another, and another, before a suitable one was found; but, in the meantime, the child was attacked with sprue and strophulus, and the bowels gave additional evidence, in their green and slimy passages, of the serious intestinal disturbance which was going on. In the hands of the last wet nurse there was considerable gain, and, hoping that change of air might push forward the improvement more rapidly, I directed the family to try the effect of a trip to the Catskill Mountains. This was done in August, but without much benefit; for, upon their return, after an absence of three weeks, the same intestinal derangement existed, and there was the additional indication of depraved nutrition in a crop of impetigo of the scalp. Once more the wet nurse was changed, and with decided benefit to the child. The supply of milk was now more plentiful and nutritious than ever before, and his general condition showed immediate signs of improvement, but still there were daily four or five greenish discharges from the bowels, containing undigested milk. Internal treatment did not seem to correct this permanently, and I resolved to make a trial of inunction. The applications of oil were directed to be made every night. Within forty-eight hours there was a diminution of the number of passages to two, instead of four or five, as had been usual for many weeks, and the color was better. Within a week the passages were normal in frequency, color, and consistency, and ever since the child has been well. The inunctions were kept up nightly for a month, and were then gradually discontinued.

These two examples have been given somewhat at length, for the purpose of illustrating the manner in which inunction may be used to relieve the two extremes of intestinal disorder which we meet with in children. The frequency of the applications varies from once an hour to once a day, according to the severity of the case, and the indications which we hope to meet by employing them. In true marasmus, and in that common form of atrophy from malnutrition which is frequently called marasmus, in rickets, and, briefly, in all conditions which are asso-

ciated with diarrhoea in children, we may find in inunction a sure and valuable remedy. I have had no experience with this method of treatment in similar conditions in adults; but on *à priori* grounds I should anticipate similar results, and in chronic dysentery or diarrhoea I should confidently look for decided relief, if not for cure, from its employment.

Diseases of the Respiratory Organs.—In acute inflammations of the lungs, pleural and bronchial tubes in children, I have several times seen most excellent effects follow from the use of inunctions. In the lobular pneumonia of children—the usual form in which pneumonia is met with in early life—there is no remedy with which I am acquainted that will so speedily induce sleep, relieve distress, and put a stop to the short moaning cry as warm sweet oil frequently applied to the whole body. This should be done two, three, or more times every day, varying with the urgency of the symptoms. Inunction is likewise of a great benefit oftentimes in chronic diseases of the lungs: phthisis, chronic pneumonia, bronchitis, and emphysema. In this connection the observations of Hirt, of Breslau, on the effects of oil fumes upon workmen are of great interest. His investigations show that the men who are employed in the reduction of the fat oils are singularly free from bronchial catarrh, and that those who enter the works with thoracic diseases and flat chests usually experience a great improvement in general health and vigor, and are no longer liable to suffer from sudden atmospheric changes. It is not unlikely that these beneficial effects are due in some measure to the absorption of oil by the skin, as well as to the inhalation of the fumes of oil, to which latter Hirt attributes all the favorable results. Inunction is sometimes effectual in controlling the night-sweats of phthisis. Its influence upon the general health in this disease is well illustrated by the following case, which Imman gives, in his colloquial style, in a chapter on oil rubbing: "I was called in consultation to see a young man, whose life to his family was very valuable. There was no doubt that he had consumption, and the sole cause of my opinion being asked was to decide whether it was better to stop in England to die, or go abroad on the chance of recovery. After many inquiries my decision was for a comfortable home until death arrived. The patient, who had twice wintered in Italy, took the same view. This being settled, the ordinary attendant said: 'Now, Doctor, is there anything which you can suggest for us to do in addition to what we are doing? Mr. — is taking chalybeates, cod oil, which he digests easily, and as good food, etc., as he can manage. As you perceive, he pays due attention to warmth and ventilation; come, what more can you think of?' I suggested oil rubbing, and the observation, 'It shall be attended to,' was the last remark about the case which I heard for a long time. About three years after this the family surgeon stopped me in the street, and asked me if I could remember Mr. —'s case? 'Yes,' was my reply, 'as distinctly as if it had occurred yesterday—how did it end?' 'Why, I met him at a ball last night, and he was the handsomest man in the room!'"

In conclusion it may be stated:

First. That the oils and fats are essential to growth and development.

Second. That inunction is a valuable method of introducing these nutritive materials into the body, to be used when the stomach will not tolerate the oils, or when we wish to produce special effects by this method of application.

Third. That the vegetable oils are more suitable than the animal oils and fats for purposes of inunction.

Fourth. That the oils and fats are chiefly useful in those diseases and derangements of the system in which wasting enters as an important factor. Hence we may expect that their employment by inunction will be specially beneficial in scrofula, constitutional syphilis, and rickets; in convalescence from acute diseases; in nervous affections; in many chronic diseases; and especially in the diseases of the chest and abdomen in children, to which reference has already been made.

Fifth. That children are more suitable subjects for inunction than adults, partly because their susceptibility to external influences is much more acute than that which is exhibited at later periods of life, and partly because the applications are more easily made upon them than upon adults.

TWO NEW DIFFERENTIAL SIGNS IN DISLOCATIONS OF THE SHOULDER.

BEING A PORTION OF A CLINICAL LECTURE DELIVERED AT BELLEVUE HOSPITAL, AFTER THE PRESENTATION OF A CASE OF SUBCORACOID DISLOCATION.

By PROF. FRANK H. HAMILTON, M.D.

THE examples of errors of diagnosis in the case of injuries involving the shoulder-joint are very frequent. My personal experience furnishes me with probably forty or fifty cases in which the head of the humerus has been supposed to be dislocated when it was not; or in which it has been supposed to be broken when it was not. For this reason it is important that you be informed of every known means of diagnosis; and to those which are already known and published I will now add two more, of which you will be able pretty often to avail yourselves.

When the head of the humerus is in its socket it projects outwards, beyond the extremity of the acromion process, from half an inch to an inch; varying more or less according to the age and size of the person. It projects also in front of the acromion process a little, but not at all behind.

In case of a dislocation, in whatever direction the head of the humerus is displaced, there can be no bony projection outwards beyond the acromion process. This fact may be ascertained always, unless there is very great swelling of the soft parts over the point of the shoulder; but it will be necessary that you should be familiar with the natural outline of the acromion process, and this is a study which medical students and medical men too much neglect, namely, the study of the natural form of the surface of the body, or what I call "Superficial Anatomy." You must learn to know where is the outer end of the clavicle, where is the outer end of the acromion process, and where is the coracoid process, if you expect to determine the existence or absence of a dislocation of the shoulder. This exercise you can pursue in your bed-rooms, on your own persons or on the persons of others. With a camel's-hair pencil, moistened with the tincture of iodine, you can mark out upon the skin the line of the clavicle, acromion process, spine of the scapula, etc. In attempting this for the first time you will probably find that there is much to learn that you did not know before, however thoroughly you have studied the anatomy of the shoulder in the dissecting-room, when the skin is removed. The same applies to all the other joints of the body; and now you will understand why some men, perhaps wholly ignorant of anatomy as it is usually taught, but familiar by long practice with superficial anatomy, will recognize in a

moment the nature of a joint injury, which you may fail after a very careful examination to detect.

Let us return to the consideration of the two special signs of shoulder-joint dislocation (liable to only one exception, as I shall hereafter explain), which I wish to add to those already given by surgical writers.

First. While the head of the humerus remains in its socket, if a rule be laid upon the outside of the arm from the shoulder to the elbow, it will not touch the acromion process, but will be distant from it at least half an inch, generally one inch or more. On the other hand, if the bone is removed from the socket, in whatever direction it may be displaced, whether forwards, downwards, or backwards, unless the shoulder is much swollen, the rule, placed in the manner above stated, will touch the acromion process.

Second. If, standing behind the patient (in case of the right shoulder) the thumb and forefinger of the left hand is made to grasp the top of the shoulder in such a manner as that the interdigital commissure shall rest upon the acromion process, just outside of the acromio-clavicular articulation; and if then the finger and thumb are dropped perpendicularly, the tip of the finger will (in case the head of the humerus is not dislocated) rest upon the centre of the round upper extremity of the humerus, as it projects in front of the acromion process, while the end of the thumb will rest upon the head of the humerus behind; but the head will be felt indistinctly by the thumb, for the reason that, instead of projecting as it does in front, it actually recedes a little beneath the acromion process. Up to this moment the surgeon may entertain some doubt whether he is actually grasping with his thumb and finger the head of the bone; but if he now moves the elbow of the injured limb forwards, so as to carry the head of the humerus backwards in its socket, he will feel it press strongly upon the thumb, and this will be conclusive. If a dislocation exists, the head of the bone cannot be felt in this situation, and by the thumb thus placed.

I have told you that both of these differential signs, in their application to shoulder-joint injuries, are liable to one exception. The phenomena would be the same, so far as these two signs are concerned, whether there was a dislocation of the head of the humerus, or a fracture with displacement of the neck of the scapula. The latter accident must, therefore, be first excluded by a careful application of the rules of diagnosis given in our treatises upon surgery; but that upon which you can most safely rely is the relative infrequency of the two accidents. It is doubtful, whether a long and active surgical practice will ever furnish you with an example of fracture of the neck of the scapula, while you will meet with a great many cases of dislocation of the shoulder.

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT graduated nineteen students at its last commencement, out of a class of fifty-one. The prize offered by the Professor of Surgery for the best written report of the surgical clinics for 1874 was awarded to Mr. J. N. Swett, of Fairfax, Vt., and honorable mention was made of the reports of A. J. Watson, and Lewis A. Arthur. The faculty have established a number of prizes, viz.: Faculty prize of \$25 for the best Thesis; a prize of \$50 for the best examination in Chemistry; a prize for the best Essay on Practical Medicine; for the best examination on Materia Medica and General Pathology, and the best written report of the lectures on Physiology.

OTITIS EXTERNA DIPHThERITICA.

By P. A. CALLAN, M.D.,

ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY, NEW YORK.

A DIPHThERITIC membrane in the external ear is a very rare complication, so rare that only one author on aural diseases, in about a dozen whom I have examined, mentions anything on the subject.

Mrs. B. M., *et.* 26, mother of two children. Three weeks previous to present attack patient noticed a slight purulent discharge from both her ears. She merely syringed them out and let "nature run her course."

The discharge continued for about two weeks' time, then ceased; but severe pain began in both ears, for which she consulted a physician, who prescribed tr. opii for ears; her suffering grew worse, she lost her appetite and could not sleep; then she tried poultices, which made the pains much worse, at times excruciating. I was then sent for. I found patient very anæmic, dejected, quite feeble, with high pulse. Her reduced condition could in part be attributed to her nursing, up to a week previous, a very large and healthy 10½ months' child. Hearing distance, left ear, ½ inch; right, on pressure heard.

I found both ears stopped up with a whitish membrane, which extended out on the concha of each, and firmly adherent to the skin. In attempting to remove a small portion of the membrane from the skin, but little force was used; still the skin bled, and the patient experienced excessive pain, and it was difficult to thoroughly remove even a small portion, it was so firmly attached.

I prescribed tonics and anodynes internally, and touched the membrane in each ear once daily with a solution of argent. nit., 120 to the ounce of water, for four days, until I entirely removed the membrane in both ears; the touching was then omitted, and hydrg. ox. nit., gr. xx. to 5 of adeps, was smeared on a piece of lint, and applied twice daily. In eight days from beginning of treatment, the ears were perfectly cured. Hearing normal. The drums were intact and had not been involved in the disease; the membrane had only occupied the outer two-thirds of each ear.

Grüber, in his *Lehrbuch der Ohrenheilkunde*, says; that the diphtheritic membrane never makes its appearance at the beginning of an otitis externa; but such a disease having lasted sometime, either through the reduced condition of the patient, or injudicious treatment, or both, the discharges cease, then a diphtheritic membrane develops itself.

ANOTHER METHOD OF PERFORATING THE DRUM MEMBRANE.

By JOSEPH SIMROCK, M.D.,

NEW YORK.

In a number of cases of chronic otitis catarrhalis media, with little or no opacity of the membrana tympani, where the Eustachian tube was pervious, and the ordinary methods of treatment had been tried unsuccessfully, I resorted, instead of puncturing the membrana tympani to a novel procedure of opening the tympanic cavity. This method consists in the application of sulphuric acid upon a selected spot of the surface of the membrana tympani, mostly on its posterior half. Such a proceeding at first sight appears hazardous, but in reality the action of this substance is wholly under control, the quantity requisite to pro-

duce a large opening being quite a minimal one. The way of applying it, is to bring the end of a fine probe, which has been covered with a thin layer of cotton and afterwards dipped into strong sulphuric acid, in contact with the surface of the membrane, either to a particular spot with a slight pressure, or by rubbing it over a larger field. In the first case an opening may be produced almost instantaneously; in the latter the fluid dries in, and, after a while, the part over which it has been spread, having become anæsthetic, may be removed by a probe like so much paper tissue. There is hardly any pain caused by the operation, and in a good many cases it might be done without the patient being aware of any operative proceeding taking place at all. The openings are of course of different size, according to the more or less limited application of the acid, but they are invariably of long persistence. It is seldom that an aperture by puncture, even of large size, does not close within two or three days. Of seventeen orifices produced by the above method, three remained open for four months; the longest time the opening took to close was twelve weeks, the shortest, thirty-one days. After closure it can be easily reopened by the same treatment, and by the result of several perforations in the same individuals, I am inclined to the belief, that by repeating the operation the regenerative power of the membrane is greatly diminished, perhaps entirely lost. In one patient the second perforation still persists in both ears since three and a half months; in another, twelve weeks; in a third, ten weeks, without visible inclination to close again. Only in three cases I have seen slight inflammation of middle and external ear follow the operation, without any disagreeable complication however. It is too soon to compare the results of this procedure with the results of puncture by the needle or of tenotomy of the tensor tympani, but I am of opinion that they will compare favorably with either. In seventeen cases the tinnitus disappeared in five; in nine it was so much diminished that patients were no longer troubled; three remained unimproved. The improvement for hearing, especially for conversation, was very manifest in six; less so in four; no improvement for hearing in seven. This procedure may also be useful in a diagnostic view; orifices made intentionally so large as to occupy one-half to three-quarters of the whole membrane enabled me in various cases to see pathological changes within the tympanic cavity: small osseous growths on the promontory, membranous bands in different places, in two cases anæsthesia of the promontory on pressure; in one case I found the entrance of the fenestra rotunda filled up with osseous matter.

After an opening has been established, syringing of the ear must be avoided, even if a slight discharge should set in.

64 EAST 12TH STREET.

CANADIAN PHARMACY.—A bill has been introduced into the Ontario Legislature, prepared by the Ontario College of Pharmacy, which requires a preliminary examination of all apprentices, and a "minor" examination of assistants, and compels them to be registered. Before commencing business as a chemist, it will be necessary not only to pass a "major" examination, but also to have been for three years an apprentice, and for two years an assistant. It is also proposed that an apprentice shall be required to pay annually a fee of one dollar, an assistant two dollars, and a chemist in business four dollars a year to the registrar, which payment shall entitle him to be enrolled as a student, associate, or member of the College, and to receive their journal.

Progress of Medical Science.

INFLAMMATION OF THE CELLULAR TISSUE IN THE RIGHT GROIN, CAUSED BY ROUND-WORMS.—RECOVERY.

—A shoemaker's boy, fourteen years old, was admitted into the hospital in Vienna, presenting a tumor the size of a goose egg in the right groin, above the inner third of Poupart's ligament. It was hard, sensitive on pressure, ill-defined towards the abdominal cavity, and the skin covering was reddened and doughy. It was not movable in any direction. There was evidence of a little deep-seated pus. The tumor was said to have made its appearance after a fall which the boy had sustained while carrying a heavy load a few days before, but it had meantime increased in size and had become more painful. In the absence of other signs of injury from the fall, the diagnosis had to be limited to an unexplained inflammation of the cellular tissue. Punctures were applied, and after two days there was distinct fluctuation over the whole surface of the tumor, and a crackling sound was appreciable, which suggested a communication with the intestine. Dr. Kumar made an incision two inches long, parallel to Poupart's ligament, and gave issue to some bubbles of air, some healthy pus free from smell, and finally a dead female round-worm. Three more worms afterwards came out alive. The patient had no recollection of ever suffering from worms before. No gas or fluid from the intestines appeared, and the wound healed at the end of six weeks.—*Bericht der K. K. Krankenanstalt Rudolph Stiftung in Wien, 1873.*

A CASE OF ABSOLUTE AMAUROSIS AFTER SUDDEN SUPPRESSION OF THE MENSES.—It was not uncommon in pre-ophthalmoscopic days to refer the occurrence of a sudden amaurosis to the arrest of some customary discharge or secretion. Of late, however, it has been questioned whether there was any such causal relation, and Von Graefe believed that thorough ophthalmoscopic examination would in such cases reveal the evidences of double retrobulbar optic neuritis. Dr. J. Samelsohn, of Cologne, believes, therefore, that much interest will attach to the case which we give in brief below.

A stout girl of twenty-one, during menstruating was one day exposed to wet, which caused an immediate stoppage of the flow. The same evening she felt a disagreeable sense of pressure in the orbits, and the pain and obscurity of vision increased so much that on the sixth morning she was totally blind. A physician applied some atropine drops, and twenty-four hours later Samelsohn found the following state of things, viz.: Absolute blindness in both eyes, no phosphenes produced by pressure, both pupils dilated to the utmost, the refractive media clear, and the fundus perfectly normal, except that the veins were apparently fuller than natural. The retina around the papilla appeared slightly grayish and highly refracting, while with the upright image it was a slight streaked; these features, however, and the fulness of the veins, remained unchanged up to the perfect recovery of the patient. There was also sensitiveness on pressing the globes back. She was treated by hot mustard foot-baths, sinapisms to the insides of the thighs, tartar-emet. in small doses, while Neurteloup's leech was applied to the temple. She afterwards had diaphoretics and pills of aloes and iron. Her sight began to improve, first in the right eye, and then in the left, the beginning of improvement in each case dating from a profuse flow of tears from the eye in question. At end of nine days she was discharged, being able to read Jaeger No. 1 with

the right eye, and No. 3 with the left. Vision soon rose to the normal in the left eye, and menstruation was re-established at the end of seven weeks from the attack. The conclusions at which Dr. Samelsohn arrived were, that the eye symptoms were probably due to a circumscribed effusion of blood, either into the substance or sheath of the trunk of the optic nerve, above the point of entrance of the arteria centralis retinae. He thinks the narration of the case may be of use in deterring the general practitioner from satisfying himself with calling such cases "hysterical," and he emphasizes the benefit of active treatment, such as was evidently of service here.—*Berl. Klin. Wochenschrift, Jan. 18, 1875.*

NEW METHOD OF PREPARING MERCURIAL OINTMENT.—The first No. of *El Estudio*, of Puebla, contains a method, proposed by D. J. Ibañez, for the preparation of mercurial ointment. The ointment is said to be equal to the best, and requires but a few minutes for its preparation. The following is the formula:—Take of lard 438 grammes, white wax 62 grammes, and rub together; take of chloride of mercury 16 grammes, and a sufficient quantity of lime-water.

Place the mercury in a marble mortar, large enough for the reception of the ingredients. Triturate with a wooden pestle, and wash the powder with lime-water several times; the resulting solution of chloride of lime is to be decanted from the powder. The transformation of the latter into oxide of mercury is indicated by its homogeneous dark color; it is then to be washed in distilled water. While quite wet, the powder is to be rubbed up with part of the cerate; then 488 grammes of purified mercury are to be added slowly while rubbing, and the whole combined with the remainder of the cerate.—*Repertoria Julisciense.*

REMOVAL OF FOREIGN BODIES FROM THE THROAT BY INJECTION.—At a meeting of the Swedish Medical Society, Dec. 22d, 1874, Dr. Lamm showed a sharp-pointed, flat bone which he had removed from the throat of a man under circumstances which contraindicated the use of forceps or the other instruments usually employed for this purpose. The method adopted was to pass a fine and very flexible catheter to a point a little distance below the seat of pain. An india-rubber syringe was connected with the catheter, and warm water injected, at first slowly, and then with increasing force. The bone was suddenly expelled, and the water which returned with it was quite clear, showing that none of it had entered the stomach. It was supposed that the lower end of the œsophagus had closed spasmodically, and the bone was loosened and floated out by the distending force of the water pressing from below upwards.—*Hygieia, Dec., 1874.*

THE LEAST SACRIFICE OF PARTS IN OPERATIVE SURGERY.—At a meeting of the Medical Society of London, held January 11th, 1875, Mr. Bryant read a paper on the above subject, which he maintained should be a leading feature of surgical practice. His point was, that in operations the surgeon is only justified in removing such portions of the body as are absolutely necessary. In speaking of the surgery of the foot, he thought we were too apt to regard any individual case as a good one for a Chopart's operation, a Pirogoff's, or a Syme's, according to our own fancy or appreciation of the value of the one or the other of these operations; and that we were too prone to forget that a good recovery of the foot might ensue on the removal of the diseased bone or bones without any amputation at all. He quoted the advocate of Syme's amputation, in Holmes's Surgery, who says, after much

experience, that "Syme's amputation is calculated to supersede entirely that of Chopart, besides taking the place of amputation of the leg in the majority of cases formerly supposed to demand it." He dissented from these views, and believed that in local disease of the foot alone, amputation should never be done until less severe measures had been employed without success; and that when amputation was called for, the minimum amount of foot should be removed.

He also stated that he believed these views applied to the surgery of the hand and other portions of the body. Cases were narrated in which suppurating and carious joints had been treated by free incisions, and the results were either partly movable joints or ankylosis. In such cases excision, or perhaps amputation, had often been practised.

In speaking of accident surgery, he maintained that only those parts that were irreparably injured should be removed, and that even doubtful portions of skin should be preserved. Mr. B. stated that he did not lay any claim to novelty in his statements, but he desired to emphasize the great principles of conservative surgery.—*Medical Press and Circular*, January 27, 1875.

MEDICAL OPHTHALMOSCOPY.—M. Bouchut, who was one of the earliest to lay stress upon the usefulness of the ophthalmoscope in medical diagnosis, has recently written in the *Gazette des Hôpitaux*, what he terms a *revue cérébroscopique* for 1874. After giving synopses of cases in which he had used the instrument, he insists upon its great value to the physician as well as to the oculist, and says, henceforth the physician may divine, and often affirm, lesions of the brain, cord, or meninges, the diagnosis of which before was impossible or only probable. Thus:

1. From hyperæmia and hyperæmic tumefaction of the optic nerve, there results the diagnosis of mechanical or inflammatory hyperæmia of the brain in meningitis, in cerebral hemorrhage, effusions into the brain, and in some cases the diagnosis of ataxic or other spinal diseases.

2. By papillary œdema joined to hyperæmia he recognizes œdema of the meninges, or an obstructed cerebral circulation, through meningitis, cerebral tumors, ventricular hydrocephalus, cerebral hemorrhage, meningeal effusions, thrombosis of the sinus, etc.

3. By neuro-retinian and choroidean anemia he recognizes cerebral hemorrhage and *ramollissement*, and if the anemia is absolute it is fatal. Empty arteries and veins of the eye, and an exsanguineous condition of the choroidean network indicate arrest of cerebral and cardiac circulation.

4. By exudative and fatty optic neuro-retinitis he recognizes chronic meningo-encephalitis, the encephalitis of cerebral tumors, and the changes in the nervous substance which accompany these tumors.

5. By retinian varices and thromboses he distinguishes meningeal thromboses or those of the sinuses.

6. By the aneurisms of the retinian arteries he recognizes the military aneurisms of the brain.

7. By simple retinian hemorrhages we recognize a compression of the brain by hemorrhagic or other effusions; but if these retinian hemorrhages are accompanied by retinian steatosis, there is also cerebral steatosis, and this is the case in chronic albuminuria, leucocythæmia, and glycosuria.

8. By atrophy of the optic nerve, tumors of the brain and cerebral or spinal sclerosis are discovered.

9. Finally, he says, tubercular granulations never exist in the choroid without similar ones in the lungs and other organs.—*Medical Times and Gazette*, Jan. 23, 1875.

RETROVERSION OF THE HEAD IN OPERATING ON THE MOUTH AND UPPER AIR-PASSAGES.—The difficulties and dangers attending bloody operations about the mouth and upper air-passages, no less than the sufferings of the patient when they are performed without anæsthetics, seem to have impressed Dr. Burow, of Königsberg. The operative procedures and apparatus proposed successively by Nussbaum, Schönborn, and Trendelenburg, embracing a preparatory tracheotomy, and then the use of various devices for tamponing the pharynx, so as to prevent the flow of blood into the bronchi during deep anæsthesia, he finds objectionable, if not even unjustifiable on surgical grounds. He therefore gladly availed himself of the method suggested by Rose for meeting these difficulties. The anæsthetic is to be administered in the ordinary position on the back, and then the head being drawn back and bent over the edge of the table until the vertex hangs vertically, is supported in this position by an assistant who kneels at one side. The operator has, of course, to make all his incisions in the reverse direction, and the blood escapes partly through the mouth, but chiefly through the nostrils. Burow gives the details of two operations which he performed in this way, the first consisting in the removal of a small tumor connected with the alveolar process of the upper jaw on the left side. Anæsthesia was easily maintained. The second operation referred to was also the second of two required in the same patient for the removal of two tumors occupying the roof of the mouth and pharynx, and connected with the soft and hard palate. The first was done without chloroform, and by the aid of the galvano-caustic loop. The second involved resection of the upper jaw. The patient swallowed no blood, and made an excellent recovery. Rose is quoted as denying from his experience any danger from this position of the head, even in old persons, and when maintained for two or three hours. With careless assistants there might possibly be danger of luxation of the cervical vertebra. The unquestionable increase of venous and capillary bleeding is claimed to be offset by the greater celerity with which the operation can be performed, from the quiet anæsthesia of the patient. Burow predicts a great future for the method.—*Berl. Klin. Wochenschr.*, Feb. 1, 1875.

SUBCUTANEOUS SYMPHYSEOTOMY IN CONTRACTED PELVIS.—Piccini claims that subcutaneous section of the fibro-cartilage of the symphysis pubis, followed by the application of the forceps, is a resource of which we may avail ourselves occasionally in the interest of both mother and child, in a pelvis whose diameter is three inches or less. He states, however, that the operation has been superseded by cephalotripsy and the induction of premature labor. He directs that the woman be laid on an inclined plane, the pelvis firmly supported, the bladder emptied by a catheter, a fold of skin taken up above the clitoris, and the cartilage then divided by a curved tenotomy knife. A starched bandage is to be applied after confinement. He says symphyseotomy is indicated in a contraction of between 2½ and 3 inches, that it should always be done subcutaneously, and the forceps applied afterwards. He claims that of 19 cases reported in Naples, 15 women and 16 children were saved.—*Allg. med. Central-Ztg.*, Feb. 3, 1875.

PERITYPHLITIS FROM PERFORATION, WITHOUT FORMATION OF A FECAL ABSCESS—RECOVERY.—A laborer, 24 years of age, was admitted into the hospital in Vienna, suffering from an elastic, painful swelling, the size of a man's fist, in the region of the cæcum. The skin was unaltered, and there was indistinct fluctuation. On the second day after his admission, Pro-

fessor Weinlechner, who had charge of the case, made an incision above Poupart's ligament, two inches to the inside of the ant. sup. spine of the ilium, and evacuated some pus, which had a faecal smell. He felt with the finger a smooth, hard body like a bean, but could not remove it. This concretion finally escaped from the wound about seven weeks after the opening of the abscess. Weinlechner's explanation of the case was, that this concretion lodged in the vermiform appendix, set up inflammation round about it and finally itself perforated the appendix and escaped into the abdominal cavity. Here it caused the abscess, while the vermiform appendix closed, so that nothing further escaped from the bowel. A week after the discharge of this body the wound was so nearly healed that the patient was discharged.—*Bricht der K. K. Krankenkunstalt Rudolph Stiftung in Wien*, 1873.

HYPERTROPHY OF THE PROSTATE.—This affection has received a great deal of attention at the hands of Dr. Axel Iversen, who has published his results in a recent monograph. He bases his description of the pathological anatomy of the disease upon 203 examinations of the prostate in persons between 36 and 83 years of age, and also upon 194 autopsies. Very full statistical evidence is thus furnished with regard to the occurrence of hypertrophy at various ages, its pathological anatomy, the extent to which it most frequently occurs, whether as partial or total, the changes it causes in the vesical orifice, urethra, etc. From the data he presents, it appears very distinctly that the disease does not occur as frequently as has hitherto been supposed; that the disposition to the affection increases markedly after the sixtieth year, and that the hypertrophy which, as a rule, may be said to be present where the weight of the organ is 25 grammes, is due histologically, sometimes to a myomatous and sometimes to a myo-adenomatous hyperplasia, which may occur more or less diffusely, or as a tumor.

The author does not corroborate the statements that have been made as to the frequent occurrence of the so-called Mercier's muscular valve; on one occasion only he saw something similar, but it proved to be a duplicature of the mucous membrane situated at the posterior border of the orifice, and barely two millimetres high; this fold disappeared, however, when the parts were viewed *in situ*, and only was seen when the urethra was slit up and the edges were stretched apart. He doubted, in fact, the existence of the peculiar fold described by Mercier, and the more as Dittel, in his numerous autopsies, had never met with such a valve. He therefore rejects this apparent barrier from the causes that produce dysuria and difficult catheterization, while he is inclined to believe that hypertrophy of the pars intermedia and the more or less prominent tumors of this region play important rôles in these regards. He lays great weight on the deformity of the orifice and on incurvation of the prostatic portion of the urethra thus caused, and explains by the changed condition of these parts the peculiar difficulties which are so often met with in the introduction of the catheter. The disease, he states, may often be present without betraying any symptoms. Good results were obtained by the injection of ergotine into the substance of the prostate.—*Ugeskrift f. Læger*, Oct., 1874.

BRYANT'S LINE AS A MEANS OF DIAGNOSIS IN INJURIES OF THE HIP.—Mr. Bryant, at a recent meeting of the Royal Medical and Chirurgical Society, read a paper on a method of diagnosing injuries of the hip, and especially impacted fracture of the neck of the femur. He described a triangle, which he called the ilio-femoral, and which was formed between the

ilium and the great trochanter of the femur. One side of it, A B, was drawn from the anterior superior spinous process of the ilium, A, to the top of the trochanter major, B; the second, A C, was drawn from the anterior superior spinous process of the ilium, A, directly downwards to the horizontal plane of the recumbent body; and third, C B, the base of the triangle, was drawn at right angles to A C, and fell upon the line A B, where it touched the great trochanter.

The line C B he regarded as the test line in shortening of the neck of the femur, either from fracture or disease, and after repeated proofs he could confidently assert that, whilst in a healthy subject the ilio-femoral triangles of the two sides were exactly similar, in all cases of injury to the hips, in which shortening of the neck of the femur existed, the amount of shortening could readily and accurately be made out on comparing the bases (C B) or the triangles of the opposite sides. In impacted fracture, where on the sound side the base of the triangle would in the adult measure its average normal length of two and a half inches, it would measure on the injured side half an inch, and perhaps an inch less.

These measurements should be taken with the patient in the horizontal position, the pelvis straight and the thighs parallel. In the discussion which ensued, several objections were made to the plan; among others, the difficulty of obtaining the perpendicular line A C on a rounded surface, as well as getting the line C B at a right angle to it, and the trouble of determining with certainty the top of the trochanter in fat persons.—*British Medical Journal*, Feb. 13, 1875.

NEVUS TREATED BY INJECTION OF THE PERCHLORIDE OF IRON.—**DEATH FROM EMBOLISM.**—Dr. West, of Birmingham, reports the following case: A child, nine months old, had a naevoid tumor of the size of a marble on the right ala nasi. It was congenital, but had increased in size since birth. Three drops of a solution of the perchloride of iron were injected with a hypodermic syringe in each of three points on the tumor. Immediately after the last of these the child's face and extremities became suddenly cyanotic, the breathing and pulse stopped, while the eyeballs were rolled upwards and outwards and the pupils were slightly dilated. Artificial respiration was used persistently for a long time, and after seven hours or more the respiration went on without assistance, and the pulse improved; the child, however, remained semicomatose and hemiplegic for three days and then died. On post-mortem examination a clot was found stretching from the right internal carotid artery into the middle cerebral, and the anterior part of the brain was softened. The case would go to confirm the views of Bryant, Thomas, Smith, and Kesteven as to the dangers of this mode of treatment, especially in naevi about the face.—*Ally. med. Central-Zty.*, Jan. 27, 1875.

EXTRAORDINARY HIGH TEMPERATURE WITH RECOVERY.—It is ordinarily held in works on thermometry, and especially by Wunderlich, that a temperature of 107.5° is incompatible with recovery; that the temperature may rise, but the rising temperature is destructive to the patient. In the *American Journal of Medical Sciences* Dr. Da Costa gives a case of recovery after a temperature of 110°. It occurred in an Irish girl, with acute rheumatism, in the Pennsylvania Hospital. The day after admission the temperature was 105.5°; two days afterwards the skin was moist, but not excessively damp; the pulse was 120, the respirations 24, the temperature 103.5°. In the evening the pulse was 104, respirations 24, and temperature 110°, two observations confirming this record.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, March 27, 1875.

WHAT IS THE LIMIT OF NEWSPAPER ADVERTISING?

WE have had a great deal to say concerning professional advertising. If there was any desire on our part of making the subject a hobby, we could have plenty of excuses for so doing. The fact, however, is, that we are forced into its discussion by the defiant manner in which some of our brethren court public notoriety. Although wishing to be decently conservative, to strain a point in professional policy, to be liberal in the interpretation of intentions, we conscientiously think that it is high time to attempt to draw the line somewhere between professional honesty and shameful quackery.

It was the custom to settle all questions bearing upon our relations with the public by our code of ethics. The rules which governed our forefathers were absolute, and from a reasonable interpretation of their spirit and letter there did not appear to be any appeal. The line was then very distinctly drawn, and the boundary of our proprieties was punctiliously respected and zealously defended. Since then, by the expansion of our influence, and by our eagerness to explode old-fogysism, we have dared to cross the Rubicon of ordinary discretion, and to-day the presumed leaders in the so-called march of progress are very uncertain where they shall stop. If any one doubts the truth of this assertion, let him count up the number of medical lectures, medical addresses, and medical papers which are published by the secular press of this city. Let him also consider that this practice of professional advertising is oftentimes carried on in the face of our societies, whose duty it is to enforce our code.

As we have often said before, we believe it to be the duty of the profession to educate the public in such professional matters as are necessary to its welfare, to teach the people the difference between legitimate medicine and blatant charlatany. We contend, how-

ever, that this can never be done by turning quacks ourselves.

Believing it to be our duty to be outspoken in this matter, we, even in this day, when newspaper advertising is timidly winked at by our County Society, dare question the right of any medical man to laud himself at the expense of his more deserving but less modest confrères. We care not who this man may be, whether a professor, a president of a society, or a leading practitioner, he is always amenable to discipline, and should, when found guilty, always be punished. If punishment cannot be inflicted without the fear of offending, then let us abolish our code of ethics, let the county societies alter their by-laws, and cease their presumptuous censorship of the profession. The Committee on Ethics may take up the case of some obscure individual, who, without influence and without friends, may be forced, in the face of starvation, to get business by unorthodox measures, and may annihilate him by expulsion. But how is it with some prominent men who presume to transgress the code with impunity? We have yet to hear of one who has ever been brought to account.

Whenever a medical man is proposed for membership to a society, there is a committee whose duty it is to inquire into his antecedents, to examine his diploma, and to take every pains to ascertain that he is a proper person for admission. The idea of any one becoming a member without a thorough examination of his standing, without the most searching scrutiny of his motives, is seemingly preposterous. To pass the ordeal of such a censorship is, conventionally speaking, a high honor. But when once the physician is admitted to membership the duties of this immaculate tribunal seem to end. The possibility of this member afterwards backsliding into questionable practices is apparently never entertained.

Let us consider what really constitutes professional advertising at the present day. We start with the assumption that it is the duty of the professional man to educate the people. We must admit that many, if not all the old prejudices concerning this necessity should be overruled. As members of a liberal profession we have no right to refuse information to the public. We can perform our duties in this respect, however, with perfect consistency and without any danger to our dignity. When we reflect how this is to be done, we can without difficulty settle upon the position of that boundary line of which we speak. So long as a man speaks for his profession as a science, and not of himself, he is in no danger of overstepping this line. His personality must be lost in the natural modesty which belongs to one who is the mere exponent of a principle. The moment he by direct assertion or by implication makes it to appear that he is more learned, more experienced, or more successful than the rest of his brethren, he becomes no better than the meanest quack. The secular papers are not disposed to make any distinction between the leader of public opinion on the gene-

ral principles of medicine, and the professional charlatan whose only aim is to advertise himself for public patronage. We cannot expect that the editors of these papers would do this, even if they were competent judges on the premises. The medical man himself is alone responsible for allowing himself to be used as a means of sensationalism in any shape. If a newspaper reporter steals an abstract of his remarks before some medical society, and publishes the same the next morning, the case is bad enough; but what have we to say to the deliberate publication in full of medical lectures and papers, in which the writers appear as the centres around which the whole constellation of medical learning, experience, and skill revolves. The shameful presumption of such individuals is only equalled by their melancholy conceit. What have we to think of a medical man who boldly asserts in an article which he consents to have published in a widely circulated secular journal, that the entire profession is wrong in the treatment of some of the commonest diseases, and that he only is right; that his profession are entirely incapable of treating these diseases; that said diseases are voted to be incurable, and that he alone is capable of managing them successfully. We are informed that a paper of this sort created such a sensation in the profession, that its publication in a secular journal was demanded. The paper did create a sensation, but only on account of the absurdity of the position assumed by the writer.

In this particular instance the gentleman who read this paper before a medical society was not even a member of that body, nor, as far as we know to the contrary, a member of any medical organization of the city. When we are informed that the paper was presented by invitation of one of the executive officers of the association after hearing it read to him privately beforehand, we may excuse the course taken on the score of an error of individual judgment; but when we consider that the members should have so quietly tolerated the unfounded insinuations, the unjust assumptions, and ridiculous pretensions of the writer, we are more than astonished. It is a matter of congratulation, however, that the association has attempted to publicly disapprove of the sentiments of the author notwithstanding that such a protest is made at the risk of adding another martyr to the long list of would-be medical reformers.

As the case now stands, the New York Medical Library Association occupies an unenviable position before the profession and the public. It is virtually made the vehicle of a professional slander, and, practically speaking, is accountable for any excuse which the author has had for giving any respectability to his newspaper article. If learned associations are so liable to be misled in matters of this sort, how can we ever expect to call individuals to account?

MEDICAL CHARITY.

THERE is no doubting the fact that the College clinics

directly encourage many of the abuses connected with medical charity. From what we can learn, patients in the rural districts who can pay their physicians at home, are getting more and more in the habit of presenting themselves for gratuitous treatment at the institutions in question than ever before. We have several letters on file detailing cases in point, in which there does not seem to be the slightest excuse on the part of the professors for even indirectly encouraging the practice. The time has come when a more rigid scrutiny should be exercised, when the fact that a patient comes from the country should be a sufficient reason why a thorough examination into his circumstances should be made. This is a very easy matter, and is an ordinary act of justice, the neglect of which is deeply felt by many country practitioners.

In one of the letters referred to, a prominent practitioner of Yonkers makes the following pertinent remarks:

"It has often been a matter of comment, both by individuals in the profession and influential journals, that a wrong is being constantly perpetrated by the hospital, dispensaries, and especially by the College clinics in New York, not only upon many practitioners in that city, but also in all the neighboring towns and villages, by prescribing for, treating, and operating upon patients at these institutions for nothing, who are perfectly well able to pay, to say nothing of the fact that such operations thus performed are construed by the public into proofs of incapacity on the part of their local practitioners; and this is done apparently without the least effort to ascertain the facts in the case."

And after referring to a simple operation recently performed at one of the clinics of the College of Physicians and Surgeons, he further says:

"The father of this child is able to pay for such a service, being the proprietor of an oyster saloon, in good business in this place, and ought to have paid for it. Furthermore, I myself had been consulted about this tumor, no great affair, some months previously, and had then explained its nature and advised its removal, and no doubt but for the facility thus offered for having it done for nothing, should have been asked to remove it. Now, sir, I am not speaking alone for myself, but for a large class of men equally wronged by such a state of things, and we think we have a just cause of complaint.

"Of what use, it may be asked, is it for any one to work long and faithfully for a local reputation, when every simple operative case is thus seized upon in the great city near by, to say nothing of the loss of the fee, no great matter, to be sure, but an injustice all the same? And with what feelings do we listen to or read the magnanimous professions, on the part of professors and lecturers, of the duty to lend a helping hand to the younger brethren of the profession when these things are going on all around us."

MEDICAL LEGISLATION IN MASSACHUSETTS.—A bill is before the Legislature of Massachusetts which provides for a Registration Board composed of two members from the Harvard Medical School, two from the State Medical Society, two Homœopaths, one Eclectic, and three appointed at large by the Governor. It has been referred to a committee, where it will probably find its quietus.

Reviews and Notices of Books.

THE COMPLETE HAND-BOOK OF OBSTETRIC SURGERY; or, Short Rules of Practice in every Emergency, etc. By CHARLES CLAY, M.D., late Senior Surgeon and Lecturer on Midwifery, St. Mary's Hospital, &c. From Third London Edition. Philadelphia: Lindsay & Blakiston, 1874, pp. 324.

A CAREFUL and trustworthy practitioner is the one who has a respect for simple details. Very often, however, in the hurry of mastering the outlines of our science in the so-called study of high art, the smaller matters are neglected. This is particularly true in the practice of midwifery. The younger practitioner who feels himself capable of performing a Caesarean section, often utterly fails to introduce a catheter. Dr. Clay's work is calculated, not only to teach every minor, and, so to speak, trivial operation of the obstetrician, but the major operations, which, for their successful performance, require the greatest amount of skill and experience. Although covering a wide range of subjects, the conciseness with which each is treated, compresses the book into manual size. To the younger practitioner this work is of great value, and will be found a ready helper in times of direst need. In a short space of time it has reached a third edition, and we see no reason why a fourth should not soon be called for. Scattered throughout the work are numerous well-executed engravings, which, together with the style of the text, give it a very attractive appearance.

A HAND-BOOK OF THERAPEUTICS. By SYDNEY RINGER, M.D. Fourth Edition. New York: Wm. Wood & Co., 1875.

DR. RINGER'S well known Hand-book has now reached its fourth edition. This is in itself a criterion of the estimation in which the work is held by the medical public, for which it was written. The present edition has the same excellences as the previous ones, and the author has incorporated the important discoveries of the year which has passed since the publication of the previous editions.

Reports of Societies.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Meeting, March 5th, 1875.

DR. LORING, VICE-PRESIDENT, in the Chair.

THE paper for the evening was read by Dr. A. McL. Hamilton, upon "Certain Changes in Nerve Structure," accompanied by illustrations with magic lantern. The specimens exhibited were chiefly those illustrating changes produced by degeneration and mechanical injury. Specimens of myelitis and sclerosis were among the more interesting. A very beautiful illustration of the distribution of the sympathetic, pneumogastric, and other nerves, was shown. An illustration of an exostosis that had perforated the Casserian ganglion was also shown.

At the close of the exhibition, Dr. Burrall called up the subject of salicylic acid, and exhibited some specimens. It appeared that no one present had had any definite experience in its use as a disinfectant.

DR. J. C. PETERS referred in this connection to experiments performed by Ledwitschi upon bacteria. The results of the experiments were that the fungi were not affected by quinine, laudanum, strychnine, or carbolic acid. Tannic acid, sulphate of iron, and all the mineral acids, however, destroyed them very quickly.

In performing his experiments two drachms of fluid were used, which swarmed with bacteria, and ordinarily ten grains of the articles were used for their destruction in solution in an equal amount or less of water.

Adjournment.

Stated Meeting, March 12, 1875.

DR. GOUVERNEUR M. SMITH, VICE-PRESIDENT, in the Chair.

ON PNEUMONIA.

DR. J. C. PETERS opened the discussion by reading a paper in which he first briefly referred to the anatomy of the lungs, embracing the ramifications of the bronchi, distribution of the capillaries, etc. He also exhibited several small plates, showing the distribution of the capillaries, the epithelial lining of the air-vesicles, and the exudation, together with its resolution, in different stages of the disease. In considering the causes of pneumonia, he remarked that the air-cells are exposed to influences coming from two directions; *first*, from without, through the air-passages; *second*, from within, through the blood. From without we have (1) intensely cold, pure, dry air, (2) cold, moist air, still pure, (3) all varieties of impure air.

From within, by way of the blood, we have effect of acute and chronic blood diseases; such as typhus and typhoid fevers, rheumatism, gout, alcoholism, Bright's disease, etc., etc.

When any of these blood poisons are at work, and the patient is exposed to some influence from without, he is much more susceptible, and pneumonia is most commonly developed under some of these circumstances. That is, mio-idiopathic pneumonia is not of common occurrence.

The essence of this part of his paper may be embraced in the statement that the system, previous to the attack of the disease, either from the condition referred to by Murchison, as lithaemia, or in consequence of failure in fibrine destroying function of the liver and digestive apparatus, or in consequence of some influence which has instituted a condition of debility more or less marked, is rendered liable to attacks of inflammatory diseases; and, under the influence of certain exciting causes, especially to the development of pneumonia.

Heart-Clot.—He regarded heart-clot as a very common cause of death; consequently, measures to prevent it should be an important factor in the treatment of the disease. How does this happen? Fibrine is present in the blood of a pneumonic patient in greater quantity than in any other disease except acute articular rheumatism. This predisposes to coagulation, and the impeded circulation through the lungs favors engorgement of the right side of the heart, and the conditions are now established favoring the formation of the clot.

Three cases were mentioned of sudden deaths occurring in patients who were convalescent from pneumonia, but insisted upon taking undue exercise, and fatal results followed. Diagnosis of heart-clot was made in all these cases previous to death.

Treatment.—When the heart begins to fail he preferred nuxvomica to quinine and stimulants; sometimes, however, he uses all of them. He also preferred ergot to digitalis.

The doctor then dwelt at some length upon the treatment adopted by Schönlein, Skoda, Fleischman, and others, which have already been reported in a previous number, under the head of reports from Academy of Medicine.

DR. L. WEBER continued the discussion. He confined his remarks entirely to the consideration of *croupous pneumonia*, and restricted them chiefly to the presentation of the views held by Prof. Jürgensen, of Tübingen.

Croupous pneumonia was defined as being an acute inflammation affecting the alveoli of the lungs and the smallest bronchi, in which an exudation is poured out upon their free surfaces more or less rich in fibrine, and coagulates when thrown out.

There is no other such inflammation of the lungs. Dr. Weber regarded Cohnheim's teaching as conclusive that some changes must take place in the walls of the capillaries before diapedesis, or migration of blood-corpules can take place.

Jürgensen claims that croupous pneumonia, unlike any other inflammation of the lungs, has a specific cause, the nature of which we do not at present know. His views are also opposed to those set forth by Boole, who claims that it is only the desquamative form of the disease, that form chiefly affecting the epithelial cells of the air vesicles, that goes on and undergoes cheesy metamorphosis.

He also claims that a great majority of fatal cases die from insufficiency of heart action, but it must not be considered that heart-clot is the cause of death; but death occurs simply in consequence of failure of the heart to perform its function, and is the first element in the process. The heart-clot that is present is secondary, and generally post-mortem, or formed just before death.

Jürgensen also regards croupous pneumonia as a constitutional, and not a local, disease. The inflammation of the lung is the principal symptom of a constitutional disturbance induced by the presence of a morbid element; hence, croupous pneumonia belongs to the class of acute infectious diseases.

The following are prominent among the proofs of this position: (1) geographical distribution shows that pneumonia is about equally distributed in different latitudes, while bronchitis, etc., are more prevalent in a northern latitude; (2) between other inflammations of the lungs and croupous pneumonia there is no agreement, so far as season of the year is concerned, with reference to frequency of occurrence; (3.) cold has nothing to do with predisposing to croupous pneumonia.

He also reasons upon the same point from anatomical considerations. Croupous pneumonia, with its coagulated exudation, is absolutely different from all other forms of inflammation of the lungs.

It cannot be produced artificially. *Clinically*, we fail (t) to notice a constant and lasting relation between the local manifestations and the constitutional disturbance, such as fever, etc. For instance, there may be a large amount of lung-tissue involved and the patient suffer comparatively but little; or again, there may be only a very small amount of lung-tissue involved by the inflammation, and the constitutional disturbance be very great.

Again, the general symptoms may suddenly subside without a corresponding retrocession of the local condition. There is no relationship between the local and general conditions. The local expression of the disease may remain while the constitutional difficulty has apparently disappeared. He therefore regards croupous pneumonia as essentially an infectious disease,

and classes it in the same category with only two other diseases, namely, acute articular rheumatism and epidemic cerebro-spinal meningitis. All three are non-contagious, and belong to the malarial class.

Of course such a view of the disease must materially influence the method of treatment. The conclusion arrived at is, that when the system is affected by some morbid element, and we have to deal with an organism made sick by it, the treatment must be sustaining until Nature has effected a cure by eliminating the poison. The moment acute croupous pneumonia is recognized as an infectious disease, the same moment we should recognize the fact that it is the duty of the physician to preserve life, if possible, until nature has been permitted to exercise her curative powers.

DR. WEBER regarded Cohnheim's observations as conclusive, that resolution cannot take place until the walls of the capillaries have been restored to their normal condition. We have therefore no remedy which has a direct effect upon the local condition, and can only affect it indirectly by sustaining the system. The special poison is not the absolute destroyer of life, the dangerous factor as in other infectious diseases like diphtheria; nothing of the kind. The danger does not lie in the intensity of the poison, but more in the lack of power the individual has to offer against it.

Lastly, the cause of death in a great majority of cases was considered.

In commenting upon this point two things were regarded as essential: (1) function of the lungs; (2) fever.

Both of these factors have an influence in weakening the heart, and the danger to life consists in that effect. That is, patients with pneumonia die because of loss of heart-power.

In treatment, therefore, we have to look at the following points particularly:

First, management of the fever; *second*, treatment must be directed towards the heart, partly prophylactic of enfeeblement, and partly when it has become enfeebled; the object being to improve this condition as much as possible.

For the fever Jürgensen uses the moderately cold bath; permitting the patient to remain in it from seven to twenty minutes, according to the degree of temperature present in the patient. His custom is to give wine before and after the baths to prevent collapse, which may occur. In feeble persons the strong wines are used. He does not always use cold, however, to reduce temperature; but in many cases resorts to quinine, and he emphasizes the manner of its administration. To adults he administers ʒss., between the hours of six and eight in the evening, and does not repeat it until forty-eight hours have elapsed.

For children up to five years of age doses of gr. iss. for each year; and from five years upwards, from 8 to 15 gr., administered in the same manner.

He has found that the action of the remedy begins from four to six hours after the administration, and will continue, showing its effects in reduction of temperature and pulse, for twelve hours. He also has found that when the dose is repeated every twenty-four hours the effects are not as striking. Given in the manner indicated it will reduce the temperature from 2° to 3°. He also supports his patients at the same time in a reasonable manner, giving wine according to symptoms and according to the individual.

There are two symptoms which are almost always present and will require attention, namely, pain and sleeplessness. For the relief of those he uses anodynes.

Sometimes the quinine is sufficient to remove all sleeplessness, particularly in children.

Jürgensen does not endorse Niemeyer's view that venesection is sometimes justifiable in consequence of collateral fluxion upon the lung unaffected; but believes that such tendency is only the beginning of paralysis of the heart, hence does not regard venesection as necessary under any circumstances. How shall we help the heart? In ordinary cases mild stimulants will be sufficient, wine, etc. In severe cases camphor is his favorite remedy. Camphor acts slow, but continues to act for some time. He uses it in from 2 to 5 grain doses every three hours, given in emulsion. In cases of sudden and severe collapse he uses musk, in doses of 1 to 2 grains every two hours, until the immediate danger is averted, and then follows up with small doses of camphor.

In this connection Dr. Weber remarked that we have no reason to be dissatisfied with the results obtained by the use of carbonate of ammonia, stimulants, etc.

Jürgensen scarcely mentions digitalis. Dr. Weber regards it as one of our most valuable agents in the treatment of this disease, and recommended it in doses sufficient to increase the power of the heart. In cases of delayed resolution, abscess, and gangrene he recommended the use of oil of turpentine in doses of ℥vi. given six times a day. In such cases this remedy in his hands had worked very well.

The papers of Drs. Peters and Weber were discussed by Drs. Sell, Messenger, Hubbard, and Foster. The views of Jürgensen will appear in a forthcoming volume of Ziemssen's *Cyclopadia*.

ACADEMY OF MEDICINE.

Stated Meeting March 4, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

THE BUILDING FOR THE ACADEMY—THE MERITS OF AMPUTATION OF LOWER THIRD OF LEG—PERIOSTEAL FLAPS.

DR. ANDERSON, of the Committee of Ways and Means, reported that \$32,500 had been paid towards the new building for the Academy. With two or three exceptions, every dollar of the money has been obtained from some member of the Academy. No time is to be lost in making it a fit building to be occupied by the Academy.

DR. STEPHEN SMITH read a paper "On the Merits, Real and Comparative, of Amputation in the Lower Third of the Leg, with Suggestions as to the Prospective Value of Periosteal Flaps." He began with a quotation from Ambrose Paré, in which was enounced a principle in operative surgery, namely, the special function of the limb should be considered, and, as far as possible, be preserved, in operation for amputation. This led him to speak of the relation that exists between the science and art of surgery, and the conclusion arrived at was, that the two are too much separated. In order to secure the greatest benefit for the patient, the mechanician should be consulted with regard to the proper point at which the operation should be performed, to enable him to adjust an artificial member to the greatest possible advantage for future usefulness. The two branches are dependent upon each other, and without their co-operation justice to the patient cannot be done.

From the time of Paré down to the present date, the old wooden peg, the old point of election, namely, amputation just below the knee, and the formation of what has been called the "poor man's stump," has

very much influenced surgeons in the performance of the operation of amputation of the leg.

It seems, however, that there has been a diversity of opinion regarding the point at which the operation should be performed; some insisting that amputation just below the knee is followed by the greatest convenience and best results; and others insisting that amputation just above the ankle is much more favorable, when it is within the power of the surgeon to make a choice.

It is probable that the most generally accepted opinion of to-day is, that the operation is to be performed at any part of the leg the surgeon may elect. There are some, however, who still prefer the old point of election, and the poor and rich man's stump. Artificial appliances and limbs are now so abundant, have been so perfected, and are so nearly within the reach of every one, that the old peg leg should have no influence upon operations of the present day.

These limbs have been so perfected, that in the lower extremities particularly, function and symmetry can be almost completely restored. In operations for amputation the surgeon should be governed (1) by the safety and life of the patient, and (2) by the serviceableness of the stump. The serviceableness of the stump is influenced (1) by point of amputation, embracing consideration for the application of an artificial limb, etc.; (2) by condition of stump; embracing the consideration of freedom from tenderness, situation of cicatrix, etc.

It is to be regarded as important that the patient shall be able to bear the weight of the body upon the stump, if possible. For if the patient is able to do this, a much more decided mechanical influence can be exercised over the artificial member.

The question now arises with reference to the part the periosteum may perform in securing such a condition of stump. Periosteal flaps have been made since the year 1860. They were first reported by a Russian surgeon. In 1862 and '63 Dr. McGill, surgeon in the U. S. A., reported several cases to the Surgeon-General. Other surgeons have also reported cases. The advantages claimed for such flaps are (1) necrosis, osteo-mylitis, and pyæmia are prevented; (2) cicatrix does not become attached to the bone; (3) stump is round and firm. The disadvantages are, liability to slough and the formation of osteophytes in the stump.

DR. SMITH presented a patient upon whom amputation had been performed just above the ankle, and the stump formed by the assistance of periosteal flaps. At the end of the fifth week the patient was able to bear very firm pressure upon the stump. The objects kept in view during the operation were (1) to cover the extremities of the bones with periosteum; (2) to make a single large flap which would completely enfold the extremity of the stump, and leave all the tissues between the periosteum and skin undisturbed. In his case the flap was made from the anterior aspect of the leg. The tissues were cut through to the bone by direct incision, and the outline of the flap made. The periosteum was then cut through, and raised with the flap. It was turned back until the upper limit of the first incision was reached, and at that point the bones were cut through with a very fine saw. Probably about half an inch of bone was uncovered of its periosteum at the angle of reflection that was not removed by the saw. No exfoliation, however, occurred.

PROFESSOR VON LEYDIG, of Tübingen, has been nominated Professor of Comparative Anatomy in the University of Bonn.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 14th to March 20th, 1875.

HEAD, J. F., Surgeon.—Relieved from duty in Department of Dakota, to proceed to Boston, Mass., and on arrival report by letter to the Surgeon-General. S. O. 44, A. G. O., March 16, 1875.

HAMMOND, J. F., Surgeon.—When relieved by Surgeon Moore, to proceed to New York City, and on arrival report by letter to the Surgeon-General. S. O. 44, c. s., A. G. O.

MOORE, JNO., Surgeon.—Relieved from duty in New York City, and to report in person to the Commanding General, Department of Texas, for duty as Medical Director. S. O. 44, c. s., A. G. O.

BILL, J. H., Surgeon.—In addition to his duties as member of Army Medical Board, to perform temporarily the duties of Attending Surgeon at Headquarters Military Division of the Atlantic. S. O. 44, c. s., A. G. O.

AZPELI, THOS. F., Assistant Surgeon.—Assigned to temporary duty at Fort Columbus, New York Harbor. S. O. 42, A. G. O., March 13, 1875.

ROSE, GEO. S., Assistant Surgeon.—To report to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 42, c. s., A. G. O.

STVER, CHAS., Assistant Surgeon.—Granted leave of absence for one month. S. O. 34, Department of the South, March 16, 1875.

SEMG, B. G., Assistant Surgeon.—Relieved from duty in the Department of California, and ordered to the Department of Arizona. S. O. 44, c. s., A. G. O.

BEALL, G. T., Medical Storekeeper.—Granted leave of absence for fourteen days. S. O. 42, c. s., A. G. O.

 Medical Items and News.

ANNUAL SALES OF "MEDICAL SPECIALTIES."—An American correspondent of the *Chemists' and Druggists' Circular* gives the following estimated value, in pounds sterling, of the annual sales of prominent patent medicines:—

Hostetter's Bitters.....	200,000
Drake's Bitters.....	140,000
Hooftland's Bitters.....	20,000
Brown's Ginger.....	50,000
Hall's Hair Renewer.....	80,000
Ayer's Pills.....	40,000
Ayer's Pectoral.....	30,000
Ayer's Aque Cure.....	20,000
Ayer's Sarsaparilla.....	30,000
Winslow's Syrup.....	100,000
Brown's Troches.....	50,000
Florida Water.....	50,000
Helmhold's Buchu.....	100,000
Kennedy's Discovery.....	20,000
Boudault's Pepsine.....	10,000
Dutcher's Fly Paper.....	10,000
Brandreth's Pills.....	30,000
Herrick's Pills.....	20,000
Schenck's Pills.....	20,000
Radway's Pills.....	40,000
Wright's Pills.....	30,000
Smith's Tonic.....	40,000
Tarrant's Aperient.....	20,000
Osgood's Cholagogue.....	20,000
Jayne's Expectorant.....	20,000
Pain-Killer.....	30,000
Sozodont.....	20,000

REPORT OF TWENTY-EIGHT CASES OF LITHOTOMY.—Dr. H. S. West, of Sivas, Turkey, writes: These are the last in a series of 143, of which I have sent an account at different times to your Journal.

Of the 28 operations, 16 were lateral and 11 median. Ages of majority of patients from two and a half to ten; of six, from thirteen to twenty. All the patients recovered. Two suffered somewhat from secondary hemorrhage, but not so as to seriously prolong recovery.

Character of stone in 22 cases, lithic or lithate; in 5 oxalic; in 2 phosphatic. All were cases of single stone, but one, in which there were two.

Weight of largest lithic concretion, eleven drachms; of largest oxalic, fifteen. In this case the patient, twenty years of age, had been a sufferer from infancy. He did remarkably well, pulse never rising after operation above 84. Most cases in which I operate have some fever on the second day.

The remaining operation was on a girl, aged five. This should have been one of lithotripsy; but I found a fistula of the urethra, resulting probably from an ineffectual effort of a native practitioner to remove the stone by the urethra. I enlarged the opening by extending the incision through the meatus, and readily removed with a polyp forceps a concretion weighing about two drachms. At last accounts there was urinary incontinence, and no doubt fistula, which will require an operation.

I will add one case of lithotripsy. Patient, a girl aged three, who had suffered much for more than a year. I crushed at first sitting, and removed several fragments, and subsequently at two different times completed the clearing of the bladder, removing in all more than three drachms of calcareous fragments. The case was doing well at last accounts.

ANOTHER CENTENARIAN.—Phebe Thomas died recently at Wilmington, Delaware, aged one hundred and four and a half years. She was a member of the Society of Friends, and the date of her birth was attested by the records of the Society. In the language of the Friends, she was born on the seventh day of the seventh month, 1770. At the age of ninety-five she was in the habit of driving about the country, alone, in her vehicle. A few years before her death her mind gave way.

PROFESSOR HESCHL, of Gratz, has been nominated Professor of Pathological Anatomy, and Professor Lieben, of Prag, Professor of Chemistry, in the University of Vienna.

THE GERMAN PUBLIC HEALTH ASSOCIATION will meet in Munich, from the 12th to the 15th of September next.

MICHIGAN STATE MEDICAL SOCIETY.—The ninth annual meeting of this Society will take place at Detroit, commencing June 9th *proximo*.

HYDROPHOBIA IN DENMARK.—Rabies exists to an alarming degree in nearly all the towns of Jutland. In Copenhagen the press is insisting upon the necessity that the Minister of the Interior should make it an offence for any one to bring a dog from Jutland to any of the islands, thus attempting to limit the disease to the peninsula, whither it has been brought, to all appearances, from Germany. There is hardly a day when the Danish papers do not cite one or more cases, and several people are reported to have died from this disease.

PROF. BENJAMIN HOWARD.—In consequence of continued ill health, Dr. Benjamin Howard, who is now in London, has resigned the Chair of Surgery in the University of Vermont.

THE CINCINNATI COLLEGE OF MEDICINE AND SURGERY graduated twenty-eight Doctors in Medicine on the 18th of February.

DR. MAYO, whom the British Government has recently appointed one of the colonial surgeons at the Fiji Islands, was formerly staff-surgeon and medical inspector in the army of the United States, staff-surgeon-major and director of the "Alice" hospital at Darmstadt during the Franco-German war, and inspecting medical officer under the Dutch during the late Atheen war.

PROFESSOR ZEISSL, of Vienna, has received the cross of Commander of the Russian Order of Stanislaus, in recognition of his services to science.

DR. LEOPOLD WITTELSÜFER, editor of the *Wiener Medizinische Wochenschrift*, has been made a knight of the Order of the North Star, by the King of Sweden and Norway.

THE THIRD ANNUAL DINNER OF THE MEDICO-LEGAL SOCIETY took place at Delmonico's on the evening of the 11th. Following the dinner, speeches were made to the following regular toasts:—"Welcome, all;" response by Clark Bell; "The Medico-Legal Society—Pills and Bills;" response by Dr. Wm. A. Hammond; "The Medical Faculty;" response by Dr. L. A. Sayre; "The Bench—The Awful Seat of Justice;" response by Judge Joseph F. Daily; "The Medical Profession;" response by Prof. A. B. Crosby; "The Bar;" response by Edward Patterson; "The Press;" response by Dr. Fuller Walker; "Our Sister Societies;" response by Dr. F. D. Lente; "The Academy of Medicine;" response by Dr. Ellsworth Eliot.

LONG ISLAND COLLEGE HOSPITAL.—The introductory lecture at the opening of the session of 1875 was given by Professor Samuel G. Armor, "Mental and Moral Epidemics" being the subject of the address.

THE BREANT PRIZE FOR THE TREATMENT OF CHOLERA.—At the annual meeting of the French Academy of Sciences, Dr. Netter received 2,000 francs as part of the Breant prize for proficiency in the treatment of cholera; and under the provisions of the Montyon prize, Drs. Fano and Mandi received honorable mentions for their medicinal and chirurgial knowledge.

WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.—The twenty-fifth annual commencement of this school took place in Philadelphia on the 11th instant, the degree of Doctor in Medicine having been conferred on sixteen graduates. The valedictory was pronounced by Professor Mary J. Scarlet Dixon, and in the evening the faculty gave a reception in the new college building.

VARIATIONS IN SKIN-MARKINGS AS A MEANS OF IDENTIFICATION.—MR. W. B. Woodbury recommends that for purposes of identification (of criminals, for example) it is only necessary to get a distinct photograph of the palm of one hand, taken in a strong oblique light, so as to bring out the markings strongly. This will be found a map, he says, never alike in two persons, and which no disguise short of actual disfigurement can do away with.

LAWS REGULATING THE PRACTICE OF MEDICINE IN GEORGIA.—The Legislature of Georgia, before its recent adjournment, passed a law creating a State Board of Health, which board is charged with the registration of births, deaths, and marriages, in addition to its general sanitary duties; and, secondly, a law granting to physicians the same right of garnishment for their fees as has previously been given to grocers and provision dealers for their security for supplies furnished to laborers.

MARK TWAIN ON THE PHYSICIANS' VIEW OF LIFE.—In one of his admirable letters to the *Atlantic Monthly* about "Old Times on the Mississippi," Mark Twain, after telling how his experience in learning steamboat piloting had changed the thoughts which had been awakened by his first knowledge of that noble river, says: "No, the romance and the beauty were all gone from the river. All the value any feature of it had for me now was the amount of usefulness furnished toward compassing the safe piloting of a steamboat. Since those days I have pitied doctors from my heart. What does the lovely flush in a beauty's cheek mean to a doctor, but a 'break' that ripples above some deadly disease? Are not all her visible charms sown thick with what are to him the signs and symbols of hidden decay? Does he ever see her beauty at all, or doesn't he simply view her professionally, and comment upon her unwholesome condition all to himself? And doesn't he sometimes wonder whether he has gained most or lost most by learning his trade?"

BUREAU OF MEDICAL AND SURGICAL RELIEF FOR OUT-DOOR POOR.—(Out-Door Department of Bellevue Hospital.) The annual report of this institution shows the following items:

New patients during 1874.....	25,591
Increase over 1873.....	3,464
Visits of patients during 1874.....	83,309
Increase over 1873.....	11,567
Prescriptions dispensed during 1874.....	88,197
Increase over 1873.....	10,389

The proportion of visits of patients in each department is as follows:—Diseases of women, 5,250; diseases of children, 15,112; diseases of the eye and ear, 2,913; diseases of the chest, 19,927; diseases of the digestive organs, 16,146; diseases of the nervous system, 2,057; diseases of the skin, 5,492; diseases of the male genitals, 4,873; department of orthopaedic surgery, 788; department of general surgery, 9,827.

CESAREAN OPERATION ON THE COW.—The veterinary surgeon Lehnert has performed this operation upon a cow affected with phthisis pulmonaris in an advanced stage, with the effect of delivering a living calf, which was successfully reared.

INFINITESIMAL DOSING.—Dr. John C. Peters, in his address on "Sects in Medicine," delivered before the New York Medico-Legal Society, says: "The Tartar physicians, or Llama doctors, have long superseded infinitesimal doses, as, if they do not happen to have any medicine with them, they are by no means disconcerted, for they merely write the name of the remedy they wish to give on a little scrap of paper, moisten this with the saliva, roll it up into a pill, which the patient tosses down his throat with the same perfect confidence as he would aloes, assafœtida, or any other remedy. To swallow the name of the remedy, or to take the medicine itself, say the Tartar physicians, by any patient, comes to precisely the same thing. If paper is not at hand, the name of the drug is written with clay or chalk upon a board, which is then washed off, and the patient swallows the liquid."

Some of our physicians even dispense with this formality, and do not give any medicine at all. They certainly have the advantage over the Tartar doctors, as they save themselves some trouble and do not run the frightful risk of misspelling the name of the drug and perchance killing the patient.

GROWTH OF CORK IN CALIFORNIA.—California is making a growing business of raising cork. There are already some artificial forests from which bark can be obtained thick enough for an ordinary cork.

A BOARD OF OFFICERS, to consist of Colonel Rufus Ingalls, Assistant Quartermaster-General; Major Alexander Chambers, Fourth Infantry, and Assistant-Surgeon George A. Otis, is appointed to meet in this city on the 1st of April to decide upon the pattern and prepare specifications for the ambulances for army use.

VACCINATION IN NEW HAVEN.—Over one thousand school children were recently vaccinated in three days in New Haven, Conn., the lymph for the purpose having been furnished by the Health Board of this city.

TYPHUS IN THE SCHOOL-SHIP MERCURY.—The school-ship Mercury, of the Department of Charities and Correction, was at Barbadoes on Feb. 14. Eight of the boys had been attacked with typhus fever. One of them, named Reilly, whose parents are supposed to reside at Avenue A and Eighth st., died on Feb. 6. The sick boys were isolated, and the rest of the crew have escaped the disease. The sick ones are said to be rapidly recovering.

MEDICAL BOARD OF BELLEVUE HOSPITAL.—At the reorganization of the Board on the 15th of March, the following officers and committees were chosen:—*President*, Dr. A. Clark; *Vice-President*, Dr. J. J. Crane; *Secretary*, Dr. E. G. Janeway; *Committee of Inspection*, Drs. Polk, Thomson, Janeway, and Clark; *Committee on Examinations*, Drs. Wood, Sands, Loomis, and Crane; *Committee on the Apothecaries' Department*, Drs. G. M. Smith and Thomson; *Committee on Records*, Drs. Wood and Clark; *Committee on Clinics*, Drs. Gouley, Sands, Janeway, and Loomis. The result of the drawing for duration of service was as follows:

To serve for seven years:—Drs. Mott, Wood, Hamilton, Sands, Delafield, Flint, G. M. Smith, and S. Smith. To serve for five years:—Drs. Gouley, Lusk, Barker, Polk, Thomson, Mason, Jacobi, and Markoe.

To serve for three years:—Drs. Sayre, Janeway, Budd, Loomis, Krackowizer, Taylor, Clark, and Crane.

THE INVENTION OF SPECTACLES.—On a tombstone in Florence is this inscription: "Here lies Salvino Armato d'Armati, of Florence, the inventor of spectacles. May God pardon his sins. The year 1318."

Dr. ERNST KRACKOWIZER has resigned his position as Visiting Surgeon in Bellevue Hospital.

BASED on the fact that in Mexico medical education is free, the schools being supported by the Government, a recent decree by a superior tribunal declared that the State had a right to the professional services of physicians when required in courts of justice. The physicians have responded that, on the same principle, as all education is free, all citizens should render their services as teachers upon the same patriotic terms.

THE PARK HOSPITAL, on Centre St., has been reported as unsafe for occupancy, owing to settling, bulging, and cracking of its walls. The Commissioners of Charities and Correction have asked the Mayor to furnish other quarters for the hospital during the time necessary for repairing the present building or constructing a new one.

THE ALUMNI ASSOCIATION OF THE MIAMI MEDICAL COLLEGE have elected the following officers for the ensuing year: *President*, Dr. W. T. Brown; *Vice-President*, Dr. J. B. Porter; *Secretary*, Dr. William Judkins; *Treasurer*, Dr. J. L. Cilley; *Executive Committee*, Drs. Wm. B. Davis, B. Stanton, J. L. Neave. The annual reunion and banquet was held on the 2d inst. at Cincinnati, when an address was delivered by Professor Wm. B. Davis on the subject of Medical Education, the ground being taken that a higher degree of culture is required, and that the standard, both for matriculants and graduates, must be raised.

DR. FRANK H. HAMILTON has resigned the Chair of "Practice of Surgery, with Operations and Clinical Surgery," in the Bellevue Hospital Medical College.

THE ADVANTAGE OF MILK DIET.—Dr. L. R. Rogers, of Albany, sends us the account of a severe case of typhoid fever, for the purpose of illustrating the milk-diet principle.

He says: "The point to which I wish to call attention is the diet part of the treatment. As soon as I felt sure that she was to have a regular "run" of fever, I commenced to give milk—fresh, raw, cow's milk from one cow—and not more than 12 hours' old at any time. I gave, during the height of the disease, from 1½ to 2 quarts per day, at every hour first, then every ½ hour, and for over two weeks every ½ hour, without any water or other food, except a few times when I tried beef-tea and other dietary preparations. The latter in every instance raised her pulse and fever, and thickened the fur on tongue. Her bowels gave no trouble, moving by injections once in four or five days, the dejections like those of an infant. Quinine and stimulants made her worse every time when tried, and the severe pain in back and limbs, which came on every day about 6 P.M., was quieted in ten or fifteen minutes by a mild current of Faradic electricity, from the back of the neck to the sacrum or feet, which was continued twenty or thirty minutes.

This treatment I used for thirty-two consecutive days, giving each time a good night's rest, free from pain, without anything in the shape of opiates. I had the best counsel the county afforded, and the case was considered by all who saw it as one of the most severe.

Small doses of the sulphite of soda was all the medicine she took that did not disagree, and I gave this simply to prevent decomposition in the milk.

There were many fatal cases in the epidemic, but all who bore milk well recovered. In this case, although she had the nourishment in 1½ to 2 quarts of the best milk, she continued to get weaker and weaker for over four weeks, which shows very plainly that any other diet would have failed to meet the emergency.

Milk contains all that is needed to nourish and keep up every part of the system nearly, and is always the same; while our best dietary mixtures are wanting in many things needed by the economy, and cannot be made twice alike. I have since that time used milk very freely in all stages of various diseases, and have had reason to be well satisfied with it as the best of any one article of diet, among both adults and children.

I do not put forth this case as one to copy from in the particular treatment, but simply to show that the best article of diet that the world contains, either in disease or convalescence, one always obtainable, and nearer alike in quality, that patients are having the same disease, to show that it is too often neglected, and complex dietary compounds used instead. The patient in this instance was confined to the house over eight weeks, and made an excellent recovery. She was thirty-six when it occurred, and is now forty-three, and has never been sick since."

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Thursday, April 1.—New York Academy of Medicine. The Pathology and Etiology of Pulmonary Phthisis in relation to its Prevention and early Arrest, by E. Darwin Hudson, Jr., M.D.

Friday, April 2.—Medical Library and Journal Association.

Saturday, April 3.—New York Medical and Surgical Society.

CASES ILLUSTRATING DIFFERENT DEGREES OF SUSCEPTIBILITY TO ELECTRICITY.

By GEORGE M. BEARD, M.D.

I APPLY the term *electro-susceptibility* to that peculiarity of the system that makes it capable of being affected for good or ill by electricity. Electro-susceptibility refers to the distant and permanent, as well as to the direct and immediate effects, of electrical treatment, and therefore differs from electro-sensibility, which is restricted mainly to the sensitiveness of the body, to electricity as evidenced during the application.

Electro-susceptibility may be subdivided into farado-susceptibility and galvano-susceptibility; some are very susceptible to the influence of the faradic and not to the galvanic, and *vice versa*; and some are very susceptible to both currents.

We recognize these different orders and modifications of susceptibility to various medicines in daily use. Thus there are many—and their number seems to be increasing—who are very susceptible to opium in any form or preparation; they cannot take even a small amount without suffering headache and nausea, and they are kept awake rather than made sleepy by it. Again, there are some who can bear and be benefited by certain preparations of opium, but not by others. Similarly, hydrate of chloral does better for some; bromide of potassium for others; and there are those who can be made to sleep only by a combination of the two remedies.

It is impossible to tell from the appearance of any patient whether he will or will not be susceptible to opium, or bromide of potassium, or alcohol; still less can we tell from personal appearance which form of opium will best and which will worst suit him, or whether bromide of potassium or hydrate of chloral will give him the best relief from insomnia.

This general law, however, holds that the nervous and delicate are more susceptible to all these powerful remedies than the phlegmatic and the strong, and that among the higher and brain-working classes smaller doses must be used and greater caution is requisite than among the lower and muscle-working classes. But both ways the exceptions are many. There are strong, large, and burly men who cannot bear opium or alcohol in any dose; there are some who can bear large quantities of alcohol, but very little of opium, and so on; and contrariwise, there are sensitive and exquisitely delicate women on whom alcohol or opium makes little impression. The range and variety of idiosyncrasy in these respects are infinite and mysterious.

In their electro-susceptibility patients similarly vary. As a general law, the higher classes bear less of electricity than the lower classes; women less than men; Americans less than Europeans; Fifth Avenue must be treated more tenderly than Five Points. And yet the exceptions to this general law are numerous and striking; there are sensitive and feeble women, in the last stages, it may be, of some severe disease, who can bear enormous doses of electricity, and there are sturdy men who can drink whiskey by the tumblerful and smoke all day, and who can easily be made miserable by a mild current applied for less than five minutes.

For some mysterious cause that may never be ex-

plained, some patients who are made worse by the faradic current in the method of general faradization, are benefited by the galvanic current in the method of central galvanization.

In some cases excellent results are obtained by alternating these methods, or by combining them in the method of galvano-faradization. In some cases I have seen advantage from using both general faradization and central galvanization at the same sitting, not simultaneously, but in succession.

In regard to this matter of susceptibility to electricity, there are three facts of great interest as well as of practical importance.

First. Children are less susceptible to electricity than adults. In experiments made during the past two years I have shown that infants of both sexes, at an extremely early age, from a few weeks or months, oftentimes, can bear almost if not quite as much electrical treatment, faradic or galvanic, central, general, or local applications, as the average adult. The immediate effect of electrical treatment of infants is to produce sleep and allay irritation, just as in adults, but more positively; the permanent effects are increase of liveliness and vigor, improvement in desire and capacity for nursing and taking food, and these permanent effects are not so often, as in adults, complicated with unpleasant effects indicating special susceptibility, whence I judge that in the infantine constitution there is some quality, or lack of quality, that renders it less susceptible to the electrical force than the constitution of adults. The one practical difficulty of making full comparison in this respect, on account of the slight intelligence of children, and their inability to observe or express their feelings, I admit of course; but when the electrical treatment produces calmness and repose in children, as in adults, it is usually, if not always safe and just to assume that all its effects are good, and only good, and that, even if the special disease is not cured, the patient will not be harmed, and, in a general way, at least, will be benefited.

Secondly. Those who are at first unpleasantly susceptible to electricity may in time become so tolerant of it as to be benefited by it.

It is important, therefore, not to be discouraged when at the beginning of a course of treatment various unpleasant symptoms occur; but to persevere, making the applications short, mild, and giving long intervals.

Thirdly. A limited number of patients in the higher walks of life can never acquire a tolerance of electricity, however cautiously it may be given, or however long the intervals between the applications. To persevere in treating such persons, after full and fair trial by very mild currents carefully given, by long intervals, is a blunder. The disagreeable effects that follow the applications, even on this class of patients, are however usually of a temporary character.

Fourthly. There are occasionally found those who are but slightly susceptible to electricity, who can bear long and strong applications, but who, notwithstanding, are not benefited by it. Of the various classes of patients with whom we have to deal, this is the most provoking; they can be treated indefinitely, and without showing any good effects of treatment; they become neither better nor worse, and no amount of perseverance seems to have any reward.

The following case shows that a delicate person may be unpleasantly susceptible to the faradic current, may bear good doses and be benefited by the galvanic current,—in other words, there may be great farado-susceptibility, and only average galvano susceptibility.

CASE I.—Miss P——, an unmarried lady of about 38 years of age, had been paralyzed for some years in the lower limbs, and withal had passed through a terrific storm of hysterical symptoms, general hyperæsthesia, insomnia, trembling, trepidation, debility in the extreme, morbid fear, and so on.

She had been treated at one time by general faradization, without important benefit. When I first saw her the symptoms were partial paralysis of the lower limbs, and great pain in the dorsal and lumbar region of the back on attempting to walk, and some insomnia. I treated her at first by local faradization of the paralyzed muscles, but this, though carefully used, seemed to irritate. I tested this question several times, and assured myself that it was not a coincidence—that she was susceptible more than is wont to the faradic current. I then tried the galvanic current centrally and locally, and found that she could bear this well and frequently, and improved under it rapidly in all her symptoms. I found that she could bear easily central galvanization with quite strong currents, applied for a considerable time, and that such treatment was followed always, or almost always, by a relief of nervousness and a disposition to sleep, and by mitigation of the hysterical pains in the back and limbs. She improved so far that she could walk about, and for a considerable distance, without the need of the mechanical support that she had formerly used.

The following case illustrates the important fact that one may be very susceptible to electricity, may indeed be harmed by a severe shock, and yet be benefited by careful management, and appreciate on the average all the well-known tonic effects of electrical treatment.

CASE II.—A young physician had been troubled for some time with neurasthenia and hypochondriasis. It was found by trial that he was quite susceptible to electricity, and it was necessary to be very moderate in the doses. Central galvanization was the method chiefly used, and under this treatment, given at considerable intervals and in conjunction with internal medication, there was an improvement in his symptoms that promised to be and has been permanent, for one year at least; but on one occasion I chanced to give him a moderately severe shock through the head, by interrupting the current when the positive pole was over the cranial centre and the negative pole at the pit of the stomach, and as a result he was put back in his progress towards recovery by at least a month. Possibly the patient, who is a medical gentleman of intelligence, may have overestimated the evil effects of this single shock, and the mind may have acted on the body, and may have reinforced a slight genuine evil by a great imagined evil; but I will admit that he was right in his opinion, and that his temporary relapse was caused by the interruption of the current through the head, and by no other agency. Such results are, however, excessively rare. I have never met with another just like it. The evil symptoms that follow such shock through the head and neck usually pass away in a few moments or hours, or at least in a day or two at most, and the patient returns to his normal condition. Very few indeed are at all injured by them. In the present case the treatment was continued after an interval, and the gentleman is, I believe, permanently better.

CASE III.—A young man, a mechanic, had been troubled with impotence for several years, the result of various excesses. His impotence was not absolute, being rather a diminution than abolition of virile power, and uncertainty in the execution.

I found that this patient could bear, without any perceptible ill effect, very powerful currents, galvanic

or faradic, applied for a long time, externally or internally. In using the urethral electrode I found that a certain portion of the canal about one inch in length had so little of electro-sensibility that strong faradization gave slight pain.

In spite of this unwonted tolerance of electricity the patient improved but very little. In the majority of cases impotence and spermatorrhœa are very much benefited by judicious electrical treatments, and in some instances the results are most gratifying; but in this case perseverance was rewarded by only a little increase of power.

The case is of interest mainly as illustrating that it is possible to be very tolerant of electricity in any form, or however administered, without showing any effect of electrical treatment. The tolerance gives no advantage. The prognosis is better when there is greater susceptibility—when there is, so to speak, something to work on—something to be done in the way of building up a sensitive and nervous constitution.

CASE IV.—A widow lady, about thirty years of age, had all her life been nervous; among very many other difficulties, had suffered from obstinate and long-standing prurigo and podalgia, or aching of the feet, with paresis of the extensors of the legs. I treated her by central galvanization, and also by localized faradization and galvanization of the parietic muscles of the aching feet. The result has been remarkable for the temporary relief of the prurigo, and the strengthening of the extensor muscles. Her catamenia came in the middle of the treatment, and lasted in all seventeen days; they were also quite profuse, and weakened her not a little. It was clear that the electricity was the cause, for previously she had been annoyed by amenorrhœa. The case was interesting also as showing that electrization of the lower limbs and feet may, by reflex action, have a most powerful effect on the pelvic organs. At no time were the applications made through or over the uterus or ovaries. At one time, when the courses had apparently stopped, electrical treatment of the feet was resumed, and at once the discharge reappeared, and for several days the flow was profuse.

In spite of these untoward experiences the lady persevered, and was rewarded by improvement of all her symptoms, of a most remarkable character.

CASE V.—The wife of a physician was treated by me for rheumatism affecting especially the shoulders, and the applications were made mainly to the shoulders and arms, and mild currents were used. The effect was to bring on a very profuse and prolonged menstruation, by which the treatment was interrupted, and it was not resumed.

In this case, as in the preceding one, the patient might have acquired a certain tolerance of electricity, and been benefited had she persevered.

Some of the reflex effects of electricity are very interesting and suggestive.

CASE VI.—A gentleman, who has for years been troubled with hyperæsthesia of the left hand and fingers on the palmar surface, appears to be very susceptible to either current, to whatever part of the body it may be applied. A very mild galvanic current causes a sense of numbness and rigidity in the affected arm and hand, and sometimes also induces a tingling or pricking in the other hand and arm.

These abnormal feelings, with many variations, may continue for several hours or days following the application. In spite of this impressibility the appetite of the patient appears to improve under the treatment, although the hyperæsthesia, which was of a troublesome character, remains the same.

SE VII.—A lady that was treated by galvanization through the lumbar region and bowels, remarked when the electrode was placed over the middle of lumbar vertebra, a peculiar sensation was felt at crown of the head—the cranial centre, as I have called it—where pain and burning sensations are so experienced by women suffering from uterine diseases, and the place where the positive pole is rested is the method of central galvanization. The reflex action takes place, we may suppose, through the spinal nerves.

In the same patient, when treated at the anus, sometimes experienced a slight thrill or transient numbness of the arms and hands. The effects were noticed when feeble galvanic currents were used, and the electrodes were placed less than a quarter of an inch from each other. The effects must then be purely reflex.

It is important to respect that in surgical as well as in medical electricity the element of the susceptibility of the patient is to be considered, and is of importance in the prognosis. It is observed that the pain accompanying various forms of malignant tumors is frequently much relieved by local galvanization; this relief appears in the midst of an application and may continue for hours, perhaps for a day or two.

With this relief of pain there may be an apparent arrest of the growth; even though it does not grow any longer it appears to stop growing larger, or at least increases more slowly than before treatment. If the tumor is ulcerating, the ulcerated surface, if treated, may put on a healthier appearance, and the quantity and quality of the discharge may be very greatly modified. There are malignant tumors, which, to the external appearance at least, are not of the ugliest type, and which are painful, but the pain is but little relieved by galvanic treatment with or without the needles, and there is no arrest of the growth. Whether the different behavior of these tumors depends on their internal structure, pathologists must determine; but the physician may justly arise whether the temperament of the patient—the electro-susceptibility—may not have something to do with these opposite results of treatment by electricity. It may be that if a tumor over which electricity had no power were transferred to another person of a different temperament, the results would be more favorable.

I have recently treated two cases of tumor of the breast, with a view to relief of pain. In one case, a more advanced and most malignant in appearance, the relief of pain, and of the uneasiness that is sometimes worse than pain, has been most grateful, and the tumor, though it had long been ulcerating, made little advance. Withal, the general vigor of the patient has improved under central applications. The patient experiences no evil effects from even strong and prolonged treatment; her temperament, without resort to any disease from which she may be suffering, is adapted for electrization. At one time she suffered from rheumatism, which was promptly and permanently relieved by galvanization.

In the other—a lady younger than the other, and as strong—a tumor of the breast, similar in the general character and malignancy, but smaller and which much earlier, has not been benefited by electrical treatment; the growth was not only not arrested, but went on rapidly. When central applications were made the patient gave evidences of unusual susceptibility to electricity. Is it not possible that if these patients could exchange their tumors, the results of treatment might be reversed.

In some cases are susceptible in a most interesting way to the hypnotic effects of electricity. I once treated

by central galvanization a young lady who almost always closed her eyes, began to nod in less than two minutes after the positive electrode was placed over the region of the sympathetic and pneumogastric, at the anterior border of the sterno-cleido-mastoid muscle. If the current were allowed to run for several minutes the patient would drop fast to sleep, but of course was easily awakened. Rapid hypnotic effects were produced also whenever the current was applied in the back or around the neck in any direction.

I have recently treated another case, where similar, though less decided hypnotic effects were obtained.

In some cases the susceptibility of patients to electricity shows itself very slowly—perhaps not until a day or two following an application. Such cases are very illusory; it takes close watching on the part of the patient, and close questioning on the part of the physician, to detect this peculiarity. Just after a séance, and very likely for several hours following each séance, the patient may feel as well as ever—possibly a little relieved—but on the evening of that day, or on the following day, the unpleasant symptoms may appear.

Cases of this kind need not be abandoned; they may be positively and permanently strengthened by cautious and faithful treatment; but they must be treated warily—sometimes by long intervals, possibly several days between the applications.

CASE OF HYDROPHOBIA.

By WILLIAM W. HEWLETT, M.D.,

BABYLON, L. I.

I was called to see the patient Feb. 1st, 1875, and obtained the following history of the case, up to the time of my visit, from the wife, who is an intelligent woman. Mr. R., aged 55, was bitten by a worthless cur of the hybrid species on the forefinger of the right and the thumb of the left hand, on Nov. 30th, 1874. The wound received no treatment beyond the application of the salves and ointments peculiar to the neighborhood. It healed in about a week. The animal had been cruelly whipped for some slight offence, but had evinced no symptoms or peculiarities that attracted observation. Unfortunately the dog was shot immediately after inflicting the bite. Mr. R. expressed fears of hydrophobia directly after receipt of the injury. Had no marked dread of the disease before. His fear was so great that it often deprived him of sleep, and he frequently remarked that the disease would be his fate. He was in feeble health for two months from repeated attacks of bronchitis and prolonged watching and attention at the bedside of an invalid mother. On the evening of Jan. 30th, 1875, he seemed greatly depressed in spirits; sighed frequently; ate no supper; felt thirsty, but drank nothing. He retired early to bed; did not sleep; would start up suddenly and appear alarmed. At 3 A.M. the following day a messenger was dispatched for medical aid, which did not arrive until 9 A.M. Meanwhile patient grew more restless and alarmed. Complained of "distress," which he referred to the cardiac and mammary regions. His medical attendant prescribed bromide of potass. and sulphat. morphia without any apparent result. He made several attempts to drink during the day, but swallowed only a small quantity of liquid, and that with great difficulty. Toward evening he grew more restless and excitable, occasionally jumped up and rushed hurriedly about the room. Was greatly shocked when asked to drink, and moaned frequently.

Overcome finally by his thirst, he attempted to drink a glass of water, which was followed immediately by violent spasms of the respiratory muscles, increasing terror and excitement.

I saw the patient first at 12.15 A.M., Feb. 1st. Found him extremely excited, eyes glaring with terror, pupils greatly dilated, imploring for help. Complained of thirst, but evinced the most terrible excitement and fear when asked to drink, or even at the sight of water. He was walking about with a hasty uncertain gait, throwing himself against his attendants and against the furniture and sides of the room. He groaned, and at times would spit violently. Respiration and circulation not accelerated except during intervals of excitement. Intellect perfectly clear. Injected morph. sulph. gr. i. in the arm with some difficulty. It had no effect beyond increasing slightly the volume of the radial pulse.

On presenting a glass of water to the patient, he would, with a tremendous effort as it were, overcome for an interval his horror, and standing erect, with muscles rigid and countenance expressing the most terrible anguish, with his chin elevated to make deglutition easier, he frantically seized the glass, and with great effort, requiring the assistance of his attendants, he carried it to his lips; but as soon as the water came in contact with the mouth he was seized with violent contractions of the laryngeal and tracheal muscles, succeeded by intense restlessness and excitement. During his excitable periods his attendants sprang away from him, as if fearing personal violence. On becoming quieter he told them he would not injure them, and begged them not to "smother" him. At 1.45 chloroform was administered. He readily and quietly came under its influence, which was continued nearly three hours. It then produced nausea, violent retching, and embarrassed respiration, which caused it to be suspended. During the greater part of the three hours he was quiet, but when only slightly under the influence of the chloroform he frequently became greatly frightened, and would jump suddenly on seeing the handkerchief that was held over his nose. As soon as the remedy was discontinued the former symptoms immediately returned, though with less severity, and he even swallowed a little beef-tea with some difficulty. Several attempts were afterward made to administer the anæsthetic, but he resisted so violently, and the spasms occurring again with increasing intensity, that it was considered prudent to relinquish it.

9 A. M. Ordered chloral hydrate gr. xl., in port wine. Found the patient feebler; spasms and restlessness continued, the former with greater intensity.

2.30 P. M. Restlessness and terror continued. Contractions not so violent. Drinks with less difficulty. Has taken half pint beef-tea, two or three glasses of water, half-pint port wine, and a cup of tea since last visit. Was quieter, but did not sleep after taking chloral.

4.45. Patient much weaker, pulse very feeble; hands and feet cold, integument clammy and shrunken; restlessness and terror continued. Groans as if in great suffering. Intellect clear.

5.20. Patient growing weaker; eyes glassy; frothing at the mouth; extreme restlessness. Intellect unimpaired.

5.50. Patient died suddenly and quietly ten minutes before, forty-eight hours after the first manifestation of symptoms of the disease.

These observations were taken and recorded at the bedside, and if the history of the case does not agree with the classical descriptions of the text-books, it is the patient's fault, not mine.

BABYON, L. I., March 11, 1875.

EARLY OPERATION FOR HARE-LIP.

By E. R. MAXSON, M.D.,

OF SYRACUSE, N. Y.

In August of 1874, at the birth of a child with a fissure of the upper lip, on the left side, extending nearly to the nose, and involving the superior maxillary and palate bones, I was requested, by very anxious parents, to operate as soon as possible for the relief of the deformity, which was really great, and to them intolerably shocking.

I selected the eighth day after birth, taking everything connected with the case, including the chances for the child and the feelings of the parents into the account, and without chloroform, being assisted only by the nurse and another lady (the grandmother). I proceeded to operate in the usual way, by detaching the upper lip from the bones behind, paring the edges of the fissure from above downwards, carrying the knife inwards, saving the bottom of the cleft to prevent a notch; detaching the upper angle with sharp scissors, passing three small silver needles through about two-thirds of the thickness of the lips, commencing at the lower angles to make the adaptation exact, applying the twisted suture, commencing with the upper needle and cementing the suture and lip by collodion, as suggested by Ferguson, applying long strips of adhesive plaster made narrow in the middle to fit between the needles, and extending back across the cheeks; and finally, by placing a compress on each cheek to aid in keeping the two parts of the cleft lip together, and to aid in approximating the divided palate and superior maxillary bones; kept in place by a roller moderately tight, passed around the head, being stitched together to prevent slipping off.

The child appeared to suffer but little during the operation, and, indeed, afterwards. The dressings kept in place, and except for the cutting of the upper adhesive plaster by the nurse, during my absence, to make the child "nurse and breathe better," as she said, no accident occurred. I removed the pins on the fourth day, and all the dressings on the fourteenth day, only a small point at the upper part having filled up by granulations, the remainder having united by adhesion before the removal of the pins and reapplying of the adhesive plasters on the fourth day.

The child appeared tolerably well, but did not grow much for several weeks. But later it commenced to grow, and now, being about six months old, it is represented as being very large and the picture of health, and presenting little or no deformity, or even marks of the operation. In fact, I believe that no one unacquainted with the *facts* has ever suspected that there had been a hare-lip, or an operation of any kind upon the child.

SYRACUSE, N. Y., March 12, 1875.

BILLS UNDER LEGISLATION.—Senator Ledwith has introduced a bill providing that the Department of Charities and Correction of this city be awarded an amount not exceeding \$50,000, for the support of adult blind persons, not inmates of any public or private institution, no person to receive more than \$50. The same bill was introduced in the Assembly by Mr. Costigan.

Mr. Thomas C. Campbell introduced in the Assembly a bill to establish and equip the building of the New York Museum of Natural History, directing the controller to issue 30-year bonds to an amount not exceeding \$300,000 to defray the cost.

AN IMPROVED FORM OF INSUFFLATOR.

By BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPARTMENT OF THE THROAT), ETC.

EVERY obstetrician has at times felt the need of a convenient and suitable insufflator, for the lungs of infants who are born in a state of semi-asphyxia, after a prolonged or difficult labor. In no one of the standard text-books of midwifery, which we have consulted, do we find such an instrument described.

In the accompanying wood-cut we see the form of an insufflator which would be, in our estimation, a real acquisition in the pocket-case of every general practitioner of medicine.

This insufflator is nothing more or less than a hollow tube, made of hard rubber, seven inches in length, and one-eighth inch in diameter, at its back extremity (1), and one-half inch at its pavilion (2). At the former end it is slightly beveled off and is curved like an ordinary tracheotomy canula.

Near the pavilion, or extremity which we place between our lips, is a small round orifice (3) on the under aspect of the tube, and just in front of this is a puppet valve (4).

If air be blown into the tube from the pavilion, the valve allows it to pass freely. When the chest walls and lungs come back on themselves during expiratory movement, the breath shuts the valve and passes out of the tube through the orifice mentioned. Again, this instrument may render good service in cases of diphtheria, or membranous croup. Tracheotomy has been performed at a late period of the disease, and asphyxia is already imminent. Now, frequently, when the operation is

terminated, the patient does not breathe immediately, and is apparently dead.

Other usual means of restoring consciousness and arresting respiration prove ineffectual, and we would have recourse to insufflation of the lungs. In our insufflator we have the means of breathing air into the lungs without incurring the obligation of placing our lips directly on the outer extremity of the tracheotomy tube, and by its use (a most important consideration) we avoid the risk of contact of diphtheritic exudation and liquids with the mucous membrane lining our buccal cavity.

15 WEST 26TH ST.

AN UNSELFISH PHYSICIAN.—On the 1st of January the streets of Paris were almost impassable, owing to the slippery ice which covered them, and the injuries which resulted from falls was numbered by hundreds. M. Loiseau, physician and member of the municipal council, was called at ten o'clock in the evening to attend a patient, and on reaching the Rue Rivoli fell twice, at first hurting his shoulder and next fracturing his leg. He was taken into a wine shop, where he remained until morning before he would permit them to call a surgeon, whom he would not be the means of exposing to the same risk. And when aid at length arrived, he insisted that the patient whom he had been called to see should first be attended to.

Reports of Hospitals.

ROOSEVELT HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

Dr. E. H. MAYNARD, HOUSE-PHYSICIAN.

ACUTE INFLAMMATORY RHEUMATISM.

ONE case had been treated in the following manner, and with results which were entirely satisfactory.

The patient was kept comfortable in bed, and received hypodermic injections of $\frac{1}{10}$ th of a grain of sulphate of atropia three times a day. No applications were made to the joints.

CHRONIC RHEUMATISM.

A case of the above presented itself the like of which every practitioner of medicine comes in contact with. When he came in, his joints were stiff, sore, more or less swollen, and he was unable to walk. The knee-joints were especially affected. He had not been cured, it is true, but had been very much benefited, so much so that he seemed well pleased. His knees were first placed in plaster-of-Paris splints, and he received hypodermic injections of sulphate of atropia. Improvement was immediate and marked. After a week or ten days the plaster dressings were removed, and the joints covered with the emplastrum ammoniaci cum hydrargyri. Sulphate of atropia continued. A goodly amount of improvement had manifested itself.

CHRONIC DYSENTERY.

Cases of chronic dysentery such as obtain in the course of phthisis or the ordinary cases of the disease have been treated of late by administering

R. Ol. ricini..... ʒ iss.

Tr. opii..... ℥xx.

M. Three times a day.

The success attending this method of treatment had been very satisfactory.

ACUTE TONSILLITIS.

When a patient suffering from this disease was admitted to the hospital one tonsil was enormously swollen, and all the symptoms indicated probable suppuration. A small blister was placed on the neck over the region of the tonsil and twenty grains of powdered guaiac administered in mucilage three times a day. On the eighth day the inflamed tonsil was very much diminished in size, and all indications of suppuration had subsided.

SYPHILIS TWENTY-THREE YEARS AFTER EXPOSURE.

A case occurred in which the initial lesion was not followed by any eruption until *twenty-three years* had elapsed. The patient then had hæmoptysis, which was followed by a syphilitic papular erythematous eruption. The eruption was disappearing under anti-syphilitic treatment.

SALICYLIC ACID FOR ULCERS.

In the surgical wards this article is now used as a dressing for ulcers, wounds, etc., etc., in the proportion of ʒ i. to ʒ lxxss. of water. So far, its substitution for carbolic acid has been agreeable and quite satisfactory.

Dr. James L. Little, of this city, has been appointed Professor of the Principles and Practice of Surgery in the Medical Department of the University of Vermont, Burlington, Vt., vice Prof. B. Howard resigned.

BELLEVUE HOSPITAL.

DIABETES MELLITUS.—CAN A DIABETIC PATIENT ELIMINATE MORE WATER THAN HE DRINKS?

A PATIENT (male) had lost 50 pounds in weight within three months, and, since his admission into the hospital had passed from 164 to 322 ounces of urine daily. Fehling's test showed that sugar was present. The point of interest was with reference to the quantity of urine passed daily, and the question arose: Can a patient eliminate more water from the body, by way of the kidneys, than he drinks?

The conviction is strong that the diabetic *may* do this; but the visiting physician remarked that, in all the cases which he had seen, where the observation had been made, the patient had taken more water than had been eliminated by the kidneys. Another exception in this man's history was absence of the voracious appetite so commonly present in this class of patients. Another casual observation made by the visiting physician is perhaps worthy of note: It is a common opinion that diabetes terminates in one of three ways—namely, either by exhaustion or consumption, or by development of pneumonia. But he had had a different experience, and that was that the kidneys undergo congestion sufficiently frequent to develop Bright's disease, and that the larger number of diabetic patients die with symptoms belonging to it. Edema, however, does not often occur.

DYSENTERY (ACUTE) AND PROLAPSUS ANI.

A female, about 45 years of age, had a sharp attack of dysentery, and, after the disease had continued for a short time, a prolapsed condition of the mucous membrane of the lower portion of the rectum was developed. The management of this particular condition was the important feature of the case. Prolapse of the rectum is of frequent occurrence in weak children, and is known by the common expression, "the body coming down." It also occurs in connection with old hemorrhoids.

The visiting physician remarked that his particular method of treatment of this case was applicable to all analogous ones, and was of special service in the treatment of prolapse of the rectum in children. First, injections under the mucous membrane of strychnia (sulphate), beginning with $\frac{1}{60}$ of a grain. In about five days it can be increased to $\frac{1}{30}$ of a grain, and afterwards $\frac{1}{4}$.

After making the injection return the intestine to the cavity of the pelvis, in the following manner:

Take an ordinary handkerchief, fold it across once, and in that fold place some pieces of coarsely powdered salt. If there is considerable inflammation present, the salt cannot be used. If the inflammation is only slight, dip the cloth, thus prepared, suddenly into water, and then quickly apply it to the protruding mass and give a gentle squeeze. Frequently this gentle squeezing alone causes the intestine to return, but almost invariably the slight irritation produced by the salt and cold water causes retraction, and the gut withdraws itself.

The injections of strychnia are to be repeated daily as long as the intestine protrudes. After the intestine ceases to protrude, the remedy may be thrown into the rectum by means of an ordinary syringe.

ARREST OF ERYSIPELAS BY MEANS OF INJECTIONS OF CARBOLIC ACID.

A case of the above was one of gunshot wound of the knee. Erysipelas invaded it and began to spread up and down the limb. The limb was girdled with hy-

podermic injections about one inch beyond the border of the erysipelatous blush. The strength of the solution used was 2 per cent. The first time the erysipelas marched over the barrier. The second line of injections arrested it, or rather the erysipelas did not spread beyond them. The house-surgeon remarked that injections of this character had evidently been of service in many cases of the same kind in his ward.

Progress of Medical Science.

A PATHOGNOMONIC SYMPTOM OF THE MORIBUND CONDITION.—Dr. John Shradly, in a paper upon the "Moribund Condition," recently read before the Yorkville Medical Association of this city, maintained that the earliest, and therefore most valuable symptom of approaching death, was the up and down movement of the trachea; that the inferior laryngeal nerve, owing to a partial paralysis, or impairment of its function, is concerned in the production of this phenomenon, and sounds the first note of alarm that the medulla oblongata is invaded.

This tracheal symptom is particularly prominent in fatal cases of uræmic convulsions, opium poisoning, apoplexy, and delirium tremens; the air then ceases to stimulate the glottis, the respiratory movements are impaired, and the lungs can no longer decarbonize the blood.

In pneumonia this symptom is of especial value, anticipating as it does alarming changes in pulse and temperature; while in phthisis, the doctor has known it to be a precursor of death three weeks in advance. Its presence or absence in membranous croup should be, in his opinion, an important element in the prognosis of a given case of tracheotomy.

ANATOMY OF THE LYMPHATIC SYSTEM.—M. Sappey claims that after many years of active search he has found the origin of the lymphatic vessels. The appearances he describes were first seen by him in studying the pepsine glands of the mucous membrane of the skate's stomach. His method consisted in injecting the lymphatic vessels by their own fluid and then coloring the fluid, in which way the capillaries and delicate networks were not altered by a foreign substance. His results are summed up as follows:

1. The lymphatics derive their origin from a system of *capillicules*, as he calls them, and by very delicate lacunæ.
2. These capillicules communicate with the blood capillaries.
3. The lymphatic system is not only an agent of absorption, but in its primary networks gives origin to the white blood-corpuscles.
4. The connective tissue, the central nervous system, and the serous membranes are unprovided with lymphatic vessels.—*La France Méd.*, 23, 1875.

CONTRIBUTIONS TO THE PATHOLOGY OF DIPHTHERIA.—Dr. Jacobi differs in so many essential points in his views concerning the pathology of diphtheria recently advanced by some of the more prominent writers upon the subject, that his able paper will be found worthy of a careful reading. The author does not regard croup and diphtheria as independent diseases. Only such differences exist as prevail generally between the sporadic and epidemic forms of the same disease. The membrane is regarded as essentially an epithelial product, and the peculiar granular amorphous material, which according to Oertel and others represents the es-

sential element in the disease and consists of bacteria, is believed by Jacobi to consist of detritus and fat molecules which are the products of degeneration of the epithelial cells. The author descants with disfavor upon the enthusiasm with which the bacteria doctrine in diphtheria has been so generally adopted, and regards it as the product of the realistic tendencies in medicine which prevail at the present time.

The subject of diphtheria is so exhaustively treated, while at the same time it is presented in such a condensed form, that a fair abstract of the entire paper is impossible. We may, however, be permitted to refer to that interesting portion where the anatomical relations of the tissues affected in diphtheria are discussed.

Diphtheria of the mucous membrane preserves, generally speaking, certain distinct characteristics in different locations. Thus Trendelenburg found by an experiment upon a rabbit that diphtheritic matter, when transplanted from the tonsil, where it was firmly and deeply embedded in the tissue, caused in the trachea deposits which were loosely attached to the mucous membrane. Now the structure of different portions of the mucous membrane which are liable to the diphtheritic deposits presents certain important variations. The epithelium may be of the pavement, cylindrical, or ciliated variety; beneath the epithelium lymphatics may be abundant or wanting, mucous glands may be present or not, elastic fibres may be numerous or absent, etc., and it is claimed that these all bear a very important relation to the development and course of the diphtheritic membrane. The elastic tissue is affected with difficulty by either chemical or organic changes, and when destroyed is only replaced by a fibrous cicatrix. "There is no elastic tissue in the mucous membrane of the nose, a large amount in the oral cavity, and particularly in the walls of the lymph follicles of the tonsils; and such an amount in the trachea that the connective-tissue fibres are in the minority." Where the elastic tissue abounds it is to be supposed that the resistance to a deep penetrating of the diphtheritic process will be great; in case the elastic tissue becomes involved, that recovery will become difficult. The kind of epithelium which is most readily affected by the diphtheritic process is the pavement. Hence beside the prominent situation of the tonsils, the structure of this epithelium predisposes them to diphtheria. The ciliated epithelium belongs to a higher grade of organic development, and hence is less liable to be destroyed. Moreover, the muciparous follicles affect the course of the pseudo-membranes in that their secretion tends to loosen the deposit and detach it from the mucous membrane. This effect is particularly seen in the trachea and respiratory part of the Schneiderian membrane.

Especial mention is made of the vocal cords. They readily afford lodgment to foreign substances, since they form the narrowest opening in the passage to the lungs. They are covered with pavement epithelium, which is the most liable to be attacked by the diphtheritic degeneration, and they have no muciparous glands. "Thus, if there is any organ predestined for diphtheria, it is the vocal cords. Where there is not poison enough for a thorough infection, there is still enough for a local deposit. Where diphtheria has died out as an epidemic, the stray cases with limited infecting power will be known for years or decennia as so-called sporadic membranous croup, as you would speak for a generation of an occasional case of sporadic cholera, or a stray case of variola. There is not infection enough to poison the throat and larynx and blood, but just sufficient for the most favorable place, the vocal cord. No speedy removal of the diphtheritic mass

can be obtained, for there are no acinous glands beneath. No general infection can spread from them, for there are no lymph-ducts to communicate it. Besides, suffocation sets in too soon for the neighboring lymph-vessels to become agents and bearers of infection in case the deposit should macerate."—*Am. Jour. of Obstetrics*, Feb., 1875.

POISONING BY HOMŒOPATHIC CAMPHOR.—Dr. George Johnson, Professor of Medicine in King's College, gives the following statement of a case under the care of Mr. Gooch. The following is Mr. G.'s history:—"About three years since I was called to see an Eton boy aged 14, who was supposed to have fainted. I found him lying on his bed, almost pulseless, and quite insensible, with his extremities cold, and his face and lips pallid. He had shortly before had his dinner, and I thought that, perhaps, he might be suffering from an attack of indigestion. Whilst I was administering stimulants, and applying hot bottles, etc., to his feet, a servant accidentally found a small bottle on his table, which was labelled, "Rubini's Homœopathic Camphor," and, thinking that he might have taken some of its contents, I gave him, with difficulty, an emetic. This had the immediate effect of causing him to vomit his dinner, which was mixed with an immense quantity of camphor, which scented the whole room most powerfully. In about half an hour he became sensible, and told me he had a cold, for which he had purchased the camphor; but, instead of dropping two or three drops on a lump of sugar, as directed, he poured it out on the sugar, and after taking it, immediately became insensible. In the evening, all the effects of the drug had gone off; he passed a good night, and had no unpleasant symptoms afterwards. He was a strong, healthy-looking boy. The bottle found in his room was very small, holding about half a drachm, and it was about half full when I saw it, so that he may have taken about fifteen drops of the solution, if an ordinary lump of sugar would hold so much."

Dr. Johnson says this is the ninth case of poisoning by the homœopathic concentrated solution of camphor which has come to his knowledge during the last two years, and suspects that if all the cases that have occurred were published, the list would be a long one, and might serve as a warning of the danger which attends the use of this highly concentrated poison.—*The British Medical Journal*, Feb. 27, 1875.

NOXIOUS AND OFFENSIVE TRADES AND MANUFACTURES, AND THE MEANS OF ABATING THE SEVERAL NUISANCES FROM THEM.—Dr. Letheby, in concluding an interesting article on the above subject, summarizes as follows his recommendations as to the best means of abating these nuisances in the manufactures which give rise to poisonous gases:

1. That all noxious and offensive operations should be carried on, as far as possible, in air-tight chambers, which can be ventilated by means of fans, or by the chimney draft.

2. That all condensable and absorbable gases and vapors should be passed through condensers and absorbents, best suited for their absorption, as water in spray, and scrubbers charged with water, oil of vitriol, or alkaline solutions.

3. That, when necessary, these scrubbers should be supplemented with special purifiers, as hydrated oxide of iron, hydrate of lime, etc.

4. That organic vapors and sulphuretted hydrogen and empyreumatic matters should be conveyed to the furnace fire and destroyed. In carrying out this part of the process, it is necessary that all steam should be

condensed from the vapors, by cooling them thoroughly before they reach the fire, as otherwise the fire is apt to be put out by them. The fire which is best suited for this purpose is that which is actually used in manufacturing operations, as special fires are very likely to be neglected; and the best place for the entrance of the noxious vapors is at the back of the ash-pit immediately under the fire-bars, as by this means a draft is secured (by closing the ash-pit), and the vapors are made to pass through the glowing coals of the fire.

5. All offensive materials should be brought to the works, or carried away from them, in properly constructed carts or tanks, which can be closely covered; and all such material when stored at the works should be kept in close tanks or chambers, ventilated, when necessary, by the scrubbers or furnace-fire. Lastly, all the operations should always be managed with care and attention to details.—*Medical Press and Circular*, February 24, 1875.

ON APOPLEXY FROM MILIARY ANEURISMS.—The views advanced a few years ago by Charcot and Bouchard, and which were confirmed in Germany by Zenker, viz., that spontaneous apoplexy of the brain depends on the bursting of small "miliary" aneurisms, has recently received the support of M. Roth, who has based his conclusions on eight post-mortem examinations. These aneurisms never exceed the size of a pin's head, and are often strung along on the vessels in great numbers something like beads. They occur most frequently in the corpus striatum, including the nucleus lentiformis and in the optic thalamus, next in frequency in the cortical part of the cerebrum, next in the mesencephalon and gray substance of the cerebellum, but very seldom in the white substance of the cerebrum or cerebellum.

Spontaneous recovery by thickening of the intima sometimes occurs, and ordinarily follows a rupture which does not involve the whole wall of the vessel, or only determines the effusion of a small amount of blood, but which frequently, and indeed most frequently in the corpus striatum and thalamus opticus, occasions abundant hemorrhages, in the midst of which the aneurism which is to blame is not to be found but only the place of rupture. Increase of pressure of the blood from hypertrophy of the left ventricle, without valvular insufficiency, is a frequent but not constant cause of this development, and can be anatomically demonstrated. The most important cause, however, consists in alterations of the walls of the vessels, the origin of which the author does not find, as other authors do, in a periarteritis or endarteritis, but in a state of diffuse cylindrical dilatation, with hypertrophy of the wall of the artery, and this condition he has often observed in advanced age in the artery of the fossa of Sylvius and its branches, and also in other arteries of the body. There now follows, when the process is much advanced, a shrinking of the media, accompanied in some cases by amyloid degeneration of the muscular coat. Subsequently, as a result of this shrinking, the circumscribed protrusions occur, and not until this period do we have the thickening of the intima or adventitia, constituting endoperiarteritis, which in some measure compensates for the shrinkage of the median coat.—*Correspondenzbl. f. Schweizer Aerzte*, No. 6, 1874.—*Berl. Klin. Wochenschr.*, Feb. 22, 1875.

NEMATOID HEMATOZOA.—In the Annual Report of the Sanitary Commissioner to the Government of India, there is an article on the above subject, by Staff-Surgeon T. R. Lewis, in continuation of his previous

observations. He calls attention to two points: 1. The chief reasons for the belief that chyluria and the elephantoid state of the tissues are associated with the presence of a microscopic hæmatozoon; and 2. In what manner, such connection being satisfactorily established, this fact can aid us in offering an explanation of the evidence we possess that the disease is due to a mechanical interruption to the flow of the nutritive fluids in the capillaries and lymphatics.

With regard to the first point, detailed histories of a number of persons affected in this manner have been published by Dr. L., and in all the *filaria sanguinis hominis* has been detected. He has traced the *filaria* to the blood directly in eleven individuals, and has detected them in one or other of the various tissues and secretions of the body in more than thirty individuals.

With reference to the second head, our knowledge is not so exact, and almost all the inferences have to be drawn from observations made in connection with the hæmatozoon described as occurring in pariah dogs. Judging from what may be seen in these, and from data derived from those post-mortem examinations which have been made of individuals affected with this parasite, Dr. L. thinks that the interference with the flow of fluid in the lymphatic capillaries and smaller blood-vessels may not unreasonably be attributed to one or other of the following causes: (1.) To tumors produced by encysted mature entozoa along the course of the blood-vessels and lymphatics, impeding the flow of fluid in them by pressure, either directly or indirectly, by interfering with the functions of the nerves supplied to the part. (2.) To the active migration of the immature, or rather partially mature, parasite, the act of perforating the tissues—nervous or vascular—producing more or less permanent lesions. (3.) To the activity of the liberated embryos in the capillaries, causing rupture of the delicate walls of these channels, in which possibly ova may have collected, owing to their size, or an aggregation of active embryos taken place, either accidentally or by the parent having migrated to the capillary termination of a blood-vessel, and there given birth to a brood of microscopic blood-worms. The walls of the capillaries once having given way, the embryos pass into the adjacent lymph channels, whose extremely delicate boundaries offer practically no impediment to the further progress of such active organisms.—*The Doctor*, March 1, 1875.

ABSENCE OF THE CORPUS CALLOSUM, WITH UNIMPAIRED INTELLIGENCE.—The following anomalies were observed by Professor Malinverni in the brain of a man who died at the age of forty, and whose mental faculties during life had been in full vigor. There was the proper proportion between the gray and the white substances, but the weight of the brain was only about 32 ounces. In external appearance the convolutions of the brain were normal, excepting that inferiorly they were less pronounced. The corpus callosum, septum lucidum, and processus cristatus of Rolando were entirely absent. In place of the corpus callosum there were four well-marked convolutions for each hemisphere. They were formed from the convolutions of Reil, which are ordinarily small and insignificant. The lateral ventricles, owing to the absence of the septum, were immediately connected; their anterior cornua, which normally are limited by the reflected portion of the corpus callosum, now extended to the anterior extremity of the anterior lobes. The remaining cornua were normal.—*Gazz. del Clin. — Schmidt's Jahrb.*, 1, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 3, 1875.

CROUP AND DIPHTHERIA.

THERE seems to be no abatement in the interest that attaches to the discussion of diphtheria in all parts of the world, and it has called forth such expressions of opinions from different sources, and the statements have been supported with so much good evidence, that it seems as if much permanent good will result. The points which have attracted the most attention have been the nature of the diphtheritic poison and the differential diagnosis of the disease. We have had occasion in a previous issue to allude to the first of these questions, in discussing the main arguments that support the parasitic theory of the disease, and we pointed out at that time the danger of misinterpreting the evidence brought forward by the friends of the theory. During the present year two English physicians of prominence have expressed their opinions boldly on the latter point, viz., the diagnosis of the disease; and, if their opinions be sustained, it will appear that we have often been using different terms for one and the same disease. We refer to membranous croup and laryngeal diphtheria, between which it is claimed a differential diagnosis is impossible.

These views are certainly not new to those who are familiar with the history of diphtheria; but they cannot be regarded as having at any time been favorably received by the majority of the English-speaking races. We shall endeavor to give a short resumé of the different views that have prevailed at different times, using as nearly as possible the language of the authors themselves. Bretonneau, the great pioneer in the field of diphtheria, stated distinctly that croup and diphtheria were one and the same disease, and that diphtheria was only the highest degree of the former. Since the time of Bretonneau there have been many epidemics, and an abundance of clinical facts have been collected which have been used by writers to show that there is a marked contrast between the two diseases. Great stress was laid upon the secondary affections, which it was

said occurred in diphtheria, but not in croup. Virchow made the apparent differences more striking by emphasizing the fact, as he stated it, that in croup the exudation lay upon the surface of the laryngeal mucous membrane, while in diphtheria it not only covered the surface, but actually invaded the mucous membrane itself, and subsequently, from lack of nourishment, the membrane was apt to become necrotic. Wagner, on the other hand, claimed that there was no such sharp anatomical distinction between the two exudations, and they were only alike in that the exudation of croup was confined to the throat, while in diphtheria it involved the other air-passages, and he claimed that the exudation was not thrown out on the surface, but was a peculiar metamorphosis or degeneration of the superficial epithelial layers. According to his experience, when persons died of diphtheria, it almost invariably happened that the exudation in the larynx was croupous, in the sense that the exudation did not involve the mucous tissue, while in the pharynx the exudation was diphtheritic, invading the mucous membrane. At intermediate points in the air-passages he believed that the exudation was partly of the croupous form and partly of the diphtheritic. In either case he found hyperæmia of the affected part, followed by transudation of serum or by hemorrhages either into the substance of the mucous membrane or upon its surface, in connection with which there was the peculiar exudation, and also an increase in the cellular elements in the mucous membrane, and sometimes in the underlying parts.

Oertel says that croup is a simple form of inflammation, in which a fibrinous exudation occurs upon the mucous membrane, and which can never pass the bounds of the local process. He believes, however, that such an exudation,—or croup, may be induced by diphtheria, as well as by other influences of nature, such as atmospheric conditions and physical and chemical causes of irritation. He also adds that the separation of the two diseases—membranous croup and diphtheria—based on anatomical and pathological grounds, is impossible, for in the severest forms of diphtheria, such as those that are followed by extensive paralyzes, the so-called croupous exudations have been found lying freely on the surface of the mucous membrane, and that if we are to consider croup as an independent form of disease from diphtheria, then we must indicate by it a purely local inflammation of the larynx and mucous membrane, called forth by different deleterious influences of many sorts, the degree of intensity of the inflammation determining whether the exudation is to be fibrinous or only sero-purulent. The points of diagnostic importance lie, he believes, in a careful estimate of the general symptoms, the affections of the glands and kidneys. The croupous inflammation will be non-contagious and sporadic. All other diagnostic points are unreliable, and in the early stages a certain diagnosis will be impossible.

These statements are in part sustained by the author-

ity of Nassiloff, who examined a case which bore the clinical traits of diphtheria. In raising the exudation from the surface of the mucous membrane he found that the epithelial layer beneath was intact, a condition which, as we have seen, has been held to be characteristic of the croupous form.

It thus appears that in seeking for a distinction between these diseases attention was at one time called to the clinical differences, at another time still to the histological structure of the membranes, and at another to the locality of the diseases. And yet Bretonneau urged that there were no clinical differences; Wagner, Nassiloff, and Oertel that the exudation was alike in both; and finally, Oertel infers that laryngeal membranous croup of the idiopathic form is not to be distinguished from laryngeal diphtheria. These views obtain additional strength from the statements of Sir William Jenner and Dr. George Johnson, the physicians already alluded to.

Jenner says that diphtheria is an acute specific disease, attended by inflammation of the pharynx, and having as its result the exudation of lymph. It is a specific inflammation arising from a specific cause. This specific inflammation has a tendency to spread over the pharynx in all directions, and in rare cases to the œsophagus and stomach. From the pharynx it may spread down into the trachea and bronchi, so that not infrequently membranous inflammation of the larynx is found. But this membranous inflammation of the larynx can in no way be distinguished from membranous croup, as far as its anatomical characters are concerned. And should, as sometimes happens, the diphtheritic exudation be limited to the larynx, there are still no means of distinguishing by the inspection of the parts whether the disease be membranous croup or laryngeal diphtheria. In alluding to the clinical characters of the two affections, he states that at one time he supposed that the presence of albumen in the urine would be sufficient evidence of diphtheria in a doubtful case, but he has since found that in what is known as true croup albumen may also be found. As to the fact that true or membranous croup does not spread, the same may sometimes be said of diphtheria. True croup is said to occur after exposure to cold and wet, and the same thing may often be said of diphtheria. These facts impel him to the belief that there is no such thing as a simple idiopathic membranous inflammation of the larynx. He believes, in fact, that the two diseases—croup and diphtheria—are identical. Dr. George Johnson, who has contributed a large number of interesting cases that tend to shed light on the origin of the disease, expresses himself strongly on this point in the diagnosis of this disease. He concurs with Bretonneau and Trousseau that all cases of so-called croup that are associated with the formation of membranes in the air-passages are essentially diphtheritic, and that, on the other hand, what is called inflammatory croup, or catarrhal laryngitis, never results in the formation of false membranes. He be-

lieves, therefore, that the distinction between membranous and diphtheritic croup is not a real one. The symptoms may vary somewhat, sometimes being severe and sometimes mild. In some the urine is highly albuminous, and in others quite free. The exudation also varies in extent and consistency, and there is great variation in the extent to which the mucous membrane and the submucous tissue become implicated in the morbid process. But he thinks that in all these outward manifestations we have only various manifestations of one and the same disease. Every variety may be met with during the same epidemic sometimes in different members of the same household. He adds, in conclusion, if there be a form of membranous croup which is neither the result of a simple inflammation nor of the diphtheritic poison, he has never met with it, nor has he any reason to believe that such a one exists.

The opinions of Dr. Jacobi, of this city, have importance in this connection. In a recent paper on the subject of diphtheria, he states that whatever clinical differences there may be between a simple membranous inflammation and constitutional diphtheria, there is no anatomical difference between the membranes wherever they make their appearance, and he also says that under the same endemic and epidemic influences a case of catarrh, a case of croup, a case of diphtheria, a case of follicular inflammation of the tonsils, may appear in the same family and in the same week, and that catarrh on the one side, and diphtheria on the other, are but the starting and terminating points between which all the different shapes and forms may be registered according to their dignity, their modification depending on individual, local, endemic, and epidemic influences. The only form which is perhaps to be excluded is the necrotizing diphtheria. He also observes that there are similar differences in the clinical characters, for the affection may be local without fever, or simply febrile, or local and obstructing, or septic, etc. The fact of the exudations being confined to the surface merely, or also invading the substance of the tissue itself, is explained by the peculiar anatomical structure of the part, such as the presence or absence of follicles, elastic tissue, etc.

From this mass of authority it seems clear that we are preparing to embrace the views of the French pathologists, and erase the name membranous croup from our nomenclature of diseases, for neither clinical nor anatomical considerations would appear to entitle it to be regarded as a distinct entity. The term croup has been a most unfortunate one; for in the first place it has left confusion in the minds of the laity, who frequently do not distinguish between the false form, or spasmodic laryngitis and the membranous form, and it has also been a source of confusion to ourselves, for the term croupous, as opposed to diphtheritic, has at one time been used to describe a clinical difference, and at another an anatomical one. The general term laryngitis would doubtless cover the whole

ground, and, with the varieties embraced under it, might be made to serve as a stand-point from which further discussion can go on. There are doubtless other forms of inflammation occurring in diphtheria, as the catarrhal and perhaps the gangrenous, for it can be shown that the membranous exudation may be preceded by the catarrhal form, and may perhaps end in the gangrenous one. In a large number of such cases, however, a diagnosis will be difficult, if not impossible, for the reasons that the attendant clinical phenomena vary exceedingly. Where, however, we find an idiopathic membranous inflammation in the larynx, it seems from our present stand-point to be proper to regard it as a case of diphtheria. In other cases the diagnosis will have to rest in a great measure on the inflammatory affections of the air-passages, chiefly of the pharynx, known exposure, constitutional symptoms, and the actual existence of an epidemic.

Reviews and Notices of Books.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY. 1874. JENNINGS & HARDHAM, 153 and 155 Market st., Newark, N. J.

THIS volume is made up of the minutes of the regular session, essays, reports of standing committees, reports of district societies, obituaries, etc. Among the items of interest we notice the Report of the Committee on Ethics and Judicial Business, to whom was referred the memorial and appeal of the twelve members expelled from the District Medical Society of the County of Hudson.

It appears that in the year 1872, twelve members of the District Medical Society for the County of Hudson were expelled.

These aggrieved members asked the Medical Society of New Jersey to reverse the decision by which they were expelled, alleging that their expulsion had been in violation of the Constitution of the District Society in several particulars.

A report accompanies the appeal, in which is set forth the injustice and unconditional procedure that form the ground of complaint, together with a history of the events preliminary to the expulsion. At the same time the appellants claim that they were expelled under an article of the Constitution of the District Medical Society, which at the last meeting of the State Society had been declared unconstitutional. Such were some of the leading considerations submitted to the State Society regarding the act of expulsion.

Those who remained under the old organization of the District Society, and sustained the expulsion of the twelve members, presented a memorial to the State Society, setting forth what they claimed to be a statement of facts, and closed their memorial by saying:

"The Society now ask the assistance of the State Medical Society in the expression of its opinion, or other recognition of this District Society, and refusal to recognize the seceders as such Society; and also such order or expression of opinion in regard to the restoration of the minute-book as may be deemed expedient, and the issuing of this Society of a duplicate charter, the original being in the possession of Dr. Culver, who declines to deliver it up to the Secretary."

Such was the desire of the memorial. The matter was referred to the Committee on Ethics and Judicial Business at the last meeting of the State Society, and in their report, published in abstract in this volume of the Transactions, is found the following language: "The evidence which was laid before the Committee discloses a long history of differences among the members of the Society, upon various matters in dispute, a consideration of which would be germane to the question raised in the memorial as to which branch of the Society shall be recognized as legitimate. The Committee believe, however, that the proceedings of the meeting of March 4th furnish all the elements necessary to a decision of the question."

The report then discusses at some length the observances and non-observances of parliamentary rules at that meeting, and closes with the following decision:

"1st. That the District Medical Society of Hudson County did not adjourn on the 4th of March, 1873, to meet in the District Attorney's room in the Court House.

"2d. The refusal of the President to entertain the appeal cannot be justified. If he believed the motion to adjourn to be in order, his refusal to put the appeal was disorderly and contumacious. If he believed it to be a nullity, his failure to preserve order, and to regulate the business of the Society, was in contempt of his constitutional duties as presiding officer.

"3d. The withdrawal of the President from the Society, with other seceding members, and their forcible and riotous abstraction of the minute-book, were acts of disorganization.

"4th. The memorialists and their associates constitute the District Medical Society for Hudson County, entitled to representation in the State Society by their delegates. They are also entitled to the book of records, and are the rightful custodians of the archives of the Society."

Signed by Drs. Wickes, Thornton, and Ryerson, Committee on Ethics and Judicial Business.

It is but fair to assume that the Committee were thorough in their investigations, and have been conscientious in their decision.

Their report bears the appearance of a document emanating from a body of men who desire to do justice in a case; and it is earnestly hoped that here will be the end of all these animosities.

"Discretion is the better part of valor," it is said; and physicians can profit by the admonition as well as the rest of mankind.

The Report of the Standing Committee upon the Medical History of the State is quite interesting, from the fact, if for no other reason, that it well illustrates how differently the same diseases are treated by different men, and also how opinions vary relative to the safety, reliability, and efficiency of certain remedial agents, and the manner of their administration.

The volume contains an engraving of the late Richard M. Cooper.

SOCIETY OF THE ALUMNI OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.—At the annual election, held March 11th, the following officers were elected: *President*, George B. Wood, M.D. *Vice-Presidents*, Jos. Carson, M.D.; Isaac Hays, M.D.; Meredith Clymer, M.D.; J. L. Atlee, M.D. *Corresponding Secretary*, R. A. Cleeman, M.D. *Treasurer*, R. E. Rogers, M.D. *Orator for 1876*, Meredith Clymer, M.D.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 18th, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

"SIGNIFICANCE OF DISTURBED ACTION AND FUNCTIONAL MURMURS OF THE HEART."

DR. JAMES R. LEAMING read a paper upon the above subject. The following is an abstract of the paper:—

In the year 1868 he had the honor of reading a paper upon Cardiac Murmurs before the New York County Med. Society, in which he endeavored to substantiate the true diagnostic sign of mitral regurgitation, and also the significance of interventricular murmurs; and that mitral regurgitation could be certainly diagnosed only by hearing a murmur in a certain region, as held by his friend the late Dr. Cammann.

Dr. Cammann had demonstrated by pathological investigations that the signs of mitral regurgitation, as generally taught, namely, the presence of murmurs at the apex of the heart, denominated blowing, sawing, rasping, etc., etc., were not reliable; but that the true, invariable sign was a murmur of an entirely different character, a soft murmur, a friction murmur, such as heard naturally when fluids are forced through comparatively small openings, and is heard behind between the seventh and eighth vertebra, close to the spine. Dr. Cammann regarded this sign as the only reliable one, and as the only one certainly diagnostic of mitral regurgitation.

In this connection the mechanism of the first sound of the heart is evidently to become a matter of great importance in diagnosing a large majority of cardiac murmurs, both functional and organic.

The theories concerning the origin of the first sound of the heart have been very numerous, and have been usually divided into those embracing conditions extrinsic and intrinsic to the heart.

Under the first head, the first sound of the heart has been attributed to impulse of the apex beat against the parietes of the chest; and under the second head it has been attributed to the noise produced by the contraction of the muscular fibres of the walls of the ventricles. This is the oldest theory.

2. That it is due to the sudden tension of the auriculo-ventricular valves.
3. Friction of the blood against the interior of the ventricle and orifice of the large arteries.
4. Sudden elevation of the segments of the valves, caused by sudden influx of a wave of blood.
5. Transmission of the concussion produced by the current of blood.

These theories and others were simply mentioned, but only three of them would engage attention.

1. Friction of the blood in the ventricle as it passes into it from the auricle.
2. Muscular contraction of the heart itself.
3. That of vibrations of the mitral valve, caused by sudden closure and tension of the valve incident to forcing and rushing of the blood in its normal circulation.

Lastly, some have believed that the first sound is the result of all three causes combined.

As none of these theories seem to accord with all those conditions present in the organ, especially with the acoustical conditions, he had been impressed with the truth that they do not give satisfactory evidence

of the real origin of the first sound, and that we must direct our attention to the heart itself for new proof.

When we come to examine the heart itself, we find within it a musical arrangement, a drum-like expansion, to which are attached tendinous chords that are held in position through the intervention of muscular fibres. It seems incredible that such admirable conditions for producing sound vibration should have been so long overlooked by so many able observers as the most probable cause for the first sound of the heart. That the first sound is produced by the vibrations of the *chorda tendinea* is a reasonable position to take, and if the doctrine can be proved by pathological evidence it will very much simplify our investigations. If plastic lymph be exuded upon the surface of the valves, and at the same time the *chorda tendinea* are shortened and thickened by the presence of plastic lymph, or glued down upon the surface of the valves so as to prevent vibration, and then, if the first sound is altered or murmurs abolished, it must be that the proof is sufficient that they are the parts directly concerned in the production of the first sound.

The following cases were offered as supplying such evidence:

CASE I.—Male, 42 years of age. During the last ten years has been dissipated; has had syphilis; had rheumatism eight years ago, and was kept in bed at that time two weeks, and has been troubled more or less since with rheumatic pains. He was as well as usual up to two years ago, when his appetite began to fail; began to vomit in the morning; weight declined from 190 lbs. to 149 lbs. He soon began to suffer from momentary attacks of unconsciousness, without falling, which continued for a number of years. During these attacks his pulse would gradually grow weaker and weaker, and finally cease. Respiration would be suspended at the same time. When he first saw the man in one of these attacks the interval of suspension of respiration and heart-beat was so long that he anxiously looked into his face to see if he were not dead. Then of a sudden a full inspiration would come, and the heart would begin to throb and continue for forty-five beats, and then cease as before.

The patient also became the subject of *petit mal*, and his epileptiform seizures came irrespective of his attacks of heart cessation.

Upon auscultation no fault in respiration was detected, and there was only a slight systolic, cardiac murmur indicative of aortic obstruction.

The sound attending the contraction of the heart, however, was peculiar, and was as if no blood was forced into the aorta by the ventricular contraction. By careful counting the exact time of heart rest, it was found to be sixteen seconds.

The heart also beat in a peculiar manner, and the area of apex beat was variable. The impulse against the chest walls was found at different times, in different places, over a space of an inch and a half in extent. Intermissions in the heart-beat occurred afterwards of extraordinary length, the chin would drop, and the friends would be fully of the opinion that the man was dead; but he would recover from these conditions of unconsciousness, and his pulse resume its accustomed rapidity, namely, twenty-five beats to the minute. His condition remained unchanged for some time, both as regards signs and symptoms.

This man finally recovered to such an extent that his pulse ran up to fifty-two beats in the minute, and continued without intermission, and he was able to walk to the office of Dr. Cammann, some little distance from his own house. Dr. Cammann expressed the opinion that the patient had a systolic obstructive

murmur, with hypertrophy of the heart; but believed the peculiar symptoms present were due to indigestion.

In Oct., 1861, the patient was taken ill again, suffered from dyspnoea, and the heart labored with only obscure physical signs.

Death occurred Nov. 26, 1861.

Post-mortem revealed complete adhesion of the pericardium to the heart, although the adhesions were somewhat firmer in some places than in others. The heart was largely hypertrophied; the curtains of the aortic valves were thickened, shortened, and incompetent, as proven by the water test.

The mitral valves were glued together; there was marked stenosis, and the opening was very small. The valve chords were thickened and covered with plastic lymph, white and glistening.

CASE II.—Female, æt. 23 years. In the case of this woman there was found a systolic murmur most distinct over the region of the aortic valves, and also a diastolic murmur. Diagnosis was aortic obstruction and regurgitation, with hypertrophy of the left ventricle. There were casts and albumen in the urine.

Post-mortem.—Kidneys—in a condition of advanced Bright's disease. Heart—hypertrophy most marked in left ventricle. Aortic valves thickened and shortened. The mitral valves, however, presented the notable feature. There was no sign of disease of this valve during life, but upon *post-mortem* the valve was found diminished in size, thickened by plastic lymph, white and opaque, the edges of the curtain narrowed and the orifice very much narrowed. The chordæ tendinæ were shortened and thickened, and the papillary muscles were also thickened to a noticeable extent.

CASE III.—This case was reported, together with the specimen, at the N. Y. Pathological Society, in 1871, by Dr. Loomis. The report can be found in THE MEDICAL RECORD for that year.

The patient was a male, 32 years of age. Had hereditary pulmonary phthisis. Had an attack of acute articular rheumatism when he was 17 years of age. From that attack he made a good recovery. Suffered no special inconvenience from that time onward, except that tobacco would cause him to suffer severely from palpitation of the heart. Some cough and expectoration of purulent and whitish material. Cough distressing at night. After a time sputa streaked with blood. One day a paroxysm of cough came on, and was attended by hæmoptysis. Loss of appetite followed soon after, night sweats came on, and emaciation. Insomnia and restlessness. Pulse about 80, regular, but quite feeble. Respiration somewhat hurried, but easily performed.

Heart action regular, but feeble, and apex beat in fifth intercostal space, and upon a level with the nipple. *No murmurs could be detected.* He suddenly became unconscious, fell from his chair, lingered for a short time, and died. *Post-mortem* revealed embolism of the middle cerebral artery and softening of brain tissue.

Heart—Weight 14 oz. Clots in the cavities on both sides. Muscular tissue relaxed. *Stenosis at the mitral orifice, and some shortening of the chordæ tendinæ.* In the anterior portion of the valve there was a bony mass, which occluded that portion of the orifice. Upon the auricular aspect the surface of the valve was ulcerated, the bony matter laid bare, and vegetations were also present. The pulmonary and tricuspid valves were normal. Moderate thickening at the base of the aorta.

The first case is full of instruction as regards functional disturbances of the heart. It shows to us that regular systolic contraction can occur, when the

auriculo-ventricular opening is contracted, as in stenosis, without producing any sound. This could be demonstrated in that case by careful auscultation, for the interval of intermission permitted such an examination as was necessary to make the demonstration.

Reference was here made to experiments performed by various experimenters, in which it has been shown that when blood is arrested from entering the cavities of the heart all sounds are extinguished, and that they return with the admission of the blood, and also that the first sound is produced when only a small quantity of blood is permitted to enter the ventricles. The fact that the first sound disappears under these circumstances, and all murmurs connected with the first sound also disappear, was regarded as an indication of sound vibrations, and is equally convincing as the hooking up of the curtain of the aortic valve is proof of the mechanism of the second sound of the heart.

The disappearance of the sound in the experiments performed, and the absence of murmurs in the first case, was because the mechanism of the first sound depends upon the situation and condition of the mitral valve and chordæ tendinæ.

The second case was under the observation of Dr. Sprague for several months, who is a careful and competent auscultator. No murmurs were detected before death, and at autopsy the conditions described were found.

The third case is also confirmatory proof, for the reason that no murmurs could be detected, and yet there were present stenosis of the mitral orifice in a marked degree, and shortening and thickening of the chordæ tendinæ.

One of the points made in his paper, read in 1868¹ was that the presystolic murmur, also called mitral direct, is one of the interventricular murmurs, and not caused by blood forced through the contracted opening due to mitral stenosis.

His arguments were that the auricle was not able to force blood through the contracted opening in such a manner as to produce a sound that may be heard through the chest-wall, even when the ventricle is empty, much less when it is filled with blood.

Another argument was, that this murmur does not occur at the time of the contraction of the auricle.

According to the best authorities, the contraction of the auricle is instantaneous, quick, and by one it is described as explosive, while the murmur is of considerable length. Again, this murmur is not of the quality of a sound produced by forcing blood through a narrow opening. But all argument becomes unnecessary in the presence of the foregoing histories and pathological specimens.

Cases were then referred to, as reported by Dr. Hamilton, of Maryland, which had a similar clinical history and pathological lesion as the cases already reported by himself, namely, no abnormal sounds indicating mitral disease before death, but at *post-mortem* extensive mitral lesions were found. Several cases of like character were referred to as reported by Prof. Dickinson and others, in which the proof seemed clear, that unless the chordæ tendinæ were in a condition favorable to produce sound, no murmurs were heard.

Bristow has reported cases in which, on the contrary, a systolic murmur was heard, and was supposed to be diagnostic of mitral regurgitation; but *post-mortem* revealed the fact that no disease of the mitral valves, orifice, or chordæ tendinæ was present.

All these murmurs may be conveniently tabulated acoustically as follows:

1. Valvular, indicative of organic disease.
2. Interventricular, both organic and functional.

Under this head we may have the organic functional and the inorganic functional.

The sound in the valvular murmurs is a friction murmur, and the interventricular murmurs are distinctly chord vibrations. There is as great a difference existing between these murmurs as there is between a whistle and the voice.

The interventricular murmurs are musical, and are almost always due to vibrations of the chordæ tendinæ usually under extraordinary tension, and the murmur is caused by rush of blood over them. They resemble every degree of pitch and tone.

Vegetations attached to the edges of the valve may produce a musical murmur; but these are very rare. The exact idea of the friction sound can be obtained by pressing upon the bulb of a rubber syringe with force, while there is a fissure in the bulb; the escape of the water through the fissure produces the sound.

It is in the same manner that the friction murmur is produced by the rush of blood through a contracted opening and over the chordæ tendinæ. When hypertrophy of the ventricle takes place there will be more or less irregular tension of the chordæ tendinæ present, and in consequence we have a blurring of the murmur, and also vibrations of string, under irregular tension, and the blood is forced against irregularly contracting muscular fibres. Cardiac murmurs are heard best over the orifices where the valves are situated, or in the direction of the vibrating column of blood. This is applicable to all the murmurs.

In mitral regurgitation the column of blood impinges against the wall of the ventricle, the impulse is communicated to the œsophagus, and through that to the intervertebral substance, and then conducted to the ear. It is heard between the seventh and eighth dorsal vertebra, and the discovery of this sound and its significance and reliability belongs to Dr. Cammann. This characteristic murmur, heard in this situation, is an un-failing sign of mitral regurgitation. This murmur is not heard in front when the valve is diseased, or at least only in exceptional cases.

He then reported a case which he believed to illustrate the possibility that it may be heard in front.

The case was one in which there was a systolic murmur at the apex beat, a soft, gushing murmur heard more to the left than to the right, and heard behind between the seventh and eighth dorsal vertebra. At that point the murmur was *shot* into the ear, as it were. It was also heard at the inner and lower angle of the scapula. One year after the first examination this murmur remained unchanged, and had the same quality in front and behind. It had none of the elements usually described as diagnostic of mitral murmurs. He believed that it was congenital, and existed without disease of the mitral valve. He also believed that many of these murmurs are not organic in the sense that the term organic murmur of the heart is generally used. Interventricular murmurs may be considered functional, inasmuch as they have their mechanism in the vibrations of the chordæ tendinæ, which are unchanged by disease. These murmurs may differ in pitch, according to the degree of the tension of the individual tendons, and the force of the heart's contraction.

The causes of difference in degrees of tension and force of heart contraction may be various. They may be dependent upon disturbed nerve power as well as organic change; hence may be produced by anæmia, disturbances of the liver and stomach; by sympathy with brain disease, and may depend upon the

influence of tobacco, coffee, tea, etc., etc., which have an influence upon the heart. Functional murmurs proper do not signify danger or death. They are alarming to the patient however, and it is no wonder that they are.

Intermittent pulse has been alluded to in the books as indicative of heart disease. But this sign of itself is no evidence of heart disease; but it is almost certain evidence of indigestion. It is true, heart disease may be productive of indigestion, but functional disturbances of the heart dependent upon dyspepsia are very much the more common.

Children commonly have intermittent pulse, especially those who are allowed very stimulating food. When the food becomes digested these intermissions will disappear. In the adult, intermissions may follow a wine dinner, with tobacco, especially during sleep.

The cause of rhythmic movements of the heart is a debatable question. That it is within the heart there can scarcely be any doubt, because the heart can be separated from the body in some of the animals, and its beats will go with the same rhythm as before removal. Still, the presence of blood and its vital connections with the body are probably essential to its perfect action.

The acoustic properties of the chest have not been studied as their importance demands. The difficulty of hearing sounds in the chest of the hunchback has been long recognized, and has been explained in almost every manner, except by recognizing the true cause, namely, that the acoustic properties of the chest have been almost entirely destroyed. In this connection he referred to the indistinctness or obliteration of cardiac murmurs, which is frequently met with when other diseases are present within the thorax, such as pneumonia and pleurisy. Why do cardiac murmurs disappear during the course of a new pleurisy? He had been led to the conclusion that it was in obedience to some physical law; for when the effusion of pleurisy or pneumonia is removed the cardiac murmurs will return. It is probably within the experience of every physician to have seen cases in which there was evidence of cardiac disease during the progress of some other thoracic disease, but no cardiac murmurs could be detected by the most careful examination; yet when such disease has disappeared the murmurs have been found.

It has been supposed that in such cases the disappearance of the murmurs was due to feebleness of heart action, but that theory he rejected; for he had seen cases in which there was thoracic disease and the pulse was *strong*, and the murmurs disappeared in the same manner as in other cases with a pulse of a different character.

The philosophical explanation of this phenomenon occurred to him in the winter of 1864, and he has now come to regard the chest as a musical chamber, which may be represented by the cavity of a violin.

When the instrument is strung, tuned, and in order, its acoustic properties may be demonstrated perfectly. If a watch be placed within or in such a violin, and the ear applied to the surface of such a chamber, every sound is heard with the most perfect clearness; but if the chamber is gradually filled with sand, while the ear still remains in contact with the surface, it will be found that the sounds will become gradually more and more muffled, and finally disappear. The observance of such phenomena is valuable, because they depend upon well-established acoustic laws. The application of the same laws in conducting our observations of phenomena within the chamber of the chest are equally scientific, and may add to our stock of scientific medicine, which is something we so much need.

At the close of the reading of the paper, Dr. J. C. Peters made a few remarks, and moved that a committee be appointed to report upon the subject-matter of the paper read by Dr. Leaming.

Discussion was continued by Drs. Hudson, O'Sullivan, and Flint.

The President appointed as committee, Drs. J. C. Peters, Flint, and Hudson.

Correspondence.

RELATIVE SITUATION OF CORPUS LUTEUM AND PLACENTA.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I desire to ask through your columns whether any of your readers have observed any constant relation between the site of the placenta and the ovary in which the corpus luteum of pregnancy is situated? In four cases where death has taken place during pregnancy, or shortly after, I have in each case remarked that the placenta was situated on the opposite side from the ovary with the corpus luteum. Of two of these I have a memorandum of this fact alone; in one of the other two the corpus luteum was in the left ovary, while in the other it was in that of the right side, the placenta being in both cases on the opposite wall of the uterus.

I am, very truly,

J. H. RAYMOND.

BROOKLYN, March 10, 1875.

ON THE TREATMENT OF EPILEPSY, BOTH NOCTURNAL AND DIURNAL, WITH THE BROMIDE TREATMENT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I notice a communication in THE MEDICAL RECORD of March 6, 1875, from Dr. James Gilliam La Roe, Jr., on his experience in treating a case of nocturnal epilepsy with bromide of potassium. I was for three years connected with the hospital for the insane at Mount Pleasant, Iowa, where we had quite a number of epileptics under treatment.

We never made any distinction in the treatment of the two forms of the disorder. We first turned our attention to the digestive apparatus, getting it into perfect order; keeping the patient upon light diet, and excluding all meats. We then commenced with Dr. Brown-Séguard's bromide ammonium mixture, (the composition of which is known to the profession), beginning with ʒi. ter die, and gradually increasing until "brominism" was produced; the convulsions generally ceased at this point, and did not again return so long as the treatment was continued. One patient we gave as high as ʒiv. of the mixture three times daily ere the convulsions ceased to recur.

When the eruption appeared (which usually follows the long-continued use of bromide of potassium), we lessened the dose.

We had one patient suffering from nocturnal epilepsy, who was quite violently insane when admitted to the hospital, but became quiet and free from epileptic paroxysms under the bromide treatment.

In all cases of epilepsy I regard it of eminent importance that the digestion of the patient be carefully observed and taken care of.

Truly yours,

JOHN H. KULP, M.D.

DAVENPORT, IOWA, March 11, 1875.

DEFECTS IN BENNETT'S SPRAY PRODUCERS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Will you allow me through your columns to say a word in explanation to those who may have purchased my spray syringes and are not able to make them work well.

In THE RECORD for Sept. 15, last, I gave a description and diagram of some instruments for spraying the larynx and posterior nares, made for me by Messrs. Tiemann & Co., according to a model designed and furnished by myself. These instruments gave such satisfaction that I thought it my duty to give them to the profession at large, which I did as above mentioned. During the past winter I have received several letters from physicians in different parts of the country, in which complaint is made that said instruments do not work well, *i. e.*, that instead of producing a fine spray, the solution with which they are charged comes from them in an unbroken stream or in jets. On calling at the manufacturers' and examining the syringes they have on hand, I find that through an oversight on the part of the workman, in some of the instruments the *long inside tube* does not reach to the end of the nozzle, and in others the *short inside tube*, which connects with the cylinder, is surrounded by a plug of hard rubber that completely occludes the calibre of the stem (outside tube) of the syringe. I cannot better explain matters than by saying that the instruments here alluded to are nothing more nor less than Richardson's atomizer, but of different forms from the original, that is, they are made on the principle of a tube within a tube. By consulting the diagram in THE RECORD of Sept. 15, any physician will be able to remedy the faulty construction of the syringe he may possess; but I am authorized to say to those who find it convenient to return their instruments to the makers, that they will be put in order at once. In conclusion, I beg to state that particular attention should be paid by the practitioner himself to the size of the hole in the tip of the nozzle; if too large or too small, a satisfactory shower of spray cannot be obtained.

Very respectfully,

W. H. BENNETT, M.D.

SPECTRUM ANALYSIS AGAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I regret that I am obliged to decline further discussion of certain points on spectrum analysis with Dr. Watermann, as I find myself unable to cope with an opponent who systematically and persistently misquotes me, misquotes himself, and misquotes authorities to whom he refers in support of his views. I complained of this in my last letter (Feb. 20), and naturally supposed that Dr. W. would exercise more care in this respect in subsequent writings. I am again disappointed. In his letter of March 20, Dr. W. denies using the word "evidently" in a certain connection. If the reader will turn to Dr. W.'s first reply to me, RECORD, Jan. 30, p. 84, third paragraph, he will find this word exactly as I quoted it in mine of Feb. 20.

In the RECORD of March 20, p. 213, second column, fourth paragraph, Dr. W. misquotes both my *words* and *meaning*, as reference to RECORD of Nov. 16, 1874, p. 605, last three lines of second paragraph, will show.

In Dr. W.'s reference (March 20) to what he appears to consider a complimentary notice of himself in the *Jahresbericht*, he *inaccurately* attributes it to *Vrchow*. The paragraph in question appears under the name of

Ackermann, Virchow being simply the editor of the journal. In quoting this paragraph, however, he omits the last *two words*, which, separated by a period from the preceding sentence (the one quoted), constitute the really important part of *Ackermann's* commentary. These words are "Nichts Neues," a phrase sufficiently expressive to those in the habit of reading the *Jahresbericht*.

HENRY G. PIFFARD, M.D.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 21st to March 27th, 1875.

DEWITT, C., Assistant Surgeon.—Granted leave of absence for one month. S. O. 37, Department of the South, March 22, 1875.

HOFF, ALEX., Assistant Surgeon.—Relieved from duty at Fort Columbus, N. Y. I., and to take station in New York City during his duty with the Army Medical Board. S. O. 50, A. G. O., March 24, 1875.

WIGGIN, A. W., Assistant Surgeon.—Died at Fort Stevens, Oregon, March 7, 1875.

Medical Items and News.

PROFESSOR VON ZIEMSSSEN, the editor of the new *Cyclopedia of Medicine*, which is now being translated into English, has had a severe attack of typhoid fever, which obliged him to try the air of Montreux. His return to Munich was expected towards the close of March.

THE NEW JERSEY STATE MEDICAL SOCIETY will hold its annual meeting at Atlantic City, on the 25th of May.

RECTAL EXPLORATION.—Dr. Weir writes: "I unintentionally omitted to state, in quoting the case of Dr. Sabine, in the article on Intra-Rectal Exploration, (RECORD of March 20th), that the cause of death was pneumonia. Will you be kind enough to correct this in your next issue, as otherwise it might be inferred that the fatal result was due to the exploration."

SEVEN young women have graduated M.D. at the Boston University School of Medicine.

IRON will be more carefully administered now; a patient who recently took a large quantity was caught stealing.

RECEPTION HOSPITAL FOR LYING-IN CASES.—On Saturday, the 27th, a resolution offered by Thomas S. Brennan, at the meeting of the Commissioners of Charities and Correction, providing a suitable place for women in labor until they can be transferred to the wards of the Charity Hospital on Blackwell's Island, was adopted. Application is to be made to the Board of Apportionment for money to carry out this plan.

RECEPTION HOSPITAL ON NINETY-NINTH STREET.—The Commissioners have decided to continue the Reception Hospital at Ninety-ninth street and Tenth avenue, there being no other hospital in the upper portion of the city.

UNIVERSITY OF LOUISIANA.—Forty-one students have just been graduated from the Medical Department of the University of Louisiana.

JOSEPH H. RAY, M.D., of Brooklyn, died on the 23d of March.

NEW YORK ACADEMY OF MEDICINE.—The Committee on Ways and Means of the Academy of Medicine have received of Mrs. Hartley (daughter of the late S. Pomeroy White, M.D.), a contribution of \$250 to the "Building Fund." This is a tribute to the memory of her father, who was an "original Fellow."

A PRIZE ESSAY.—Dr. R. N. Taylor, of Maysville, Ky., won the prize offered by John P. Morton & Co., publishers, of Louisville, Ky., for the best thesis on some subject connected with *materia medica*. The title of his paper was "The Physiological Action of *Gelsemium Sempervirens*."

A REMEDY FOR BURNS.—Dr. S. Galentine, of Neenah, Wisconsin, treats burns very successfully by painting them with a solution of subsulphate of iron in water. By that means a healthy scab is formed, which remains until the healing process is complete.

"PUNCH" ON HOLLOWAY'S ASYLUM.—*Punch* furnishes this inscription for the front of the idiot asylum founded by Mr. Holloway, who made his fortune in "patent medicines":—

"Not oft is fate so just—see wealth restored
Back to the simple source from which it poured."

TRICHINÆ, according to a Nordhausen paper, have recently been found, on microscopic examination, for the first time, in the flesh of a wild boar. Hitherto it has been believed that these parasites infected the domestic pig alone.

SALICYLIC ACID sells in this city for eighty cents per ounce.

TWIN PREGNANCY AFTER OVARIOTOMY.—In July of 1871, Professor Marzolo, of Padua, performed ovariectomy successfully upon a woman of thirty-four, removing the left ovary. At the end of the year she became pregnant, and was delivered at term of a girl, who presented by the head, and a few minutes later of a boy, who presented by the breech. Labor lasted but two hours.—*Edin. Med. Jour.*, Jan. 1874.—*Rundschau*, Dec. 1874.

MEDICAL INSPECTOR DELAVAN BLOODGOOD, U.S.N., has been assigned to duty at the Brooklyn Navy Yard, and Surgeon C. J. S. Wells to the iron-clad steamer "Roanoke," in New York harbor. Medical Director F. M. Gunnell, lately on special duty at the New York Station, is ordered as member of the Naval Medical Examining Board at Washington, D.C. The Examining Board will continue in session through the next two or three months, for the convenience of candidates for admission to the Medical Corps of the Navy who have but recently obtained their degrees, and who may desire a bit of "coaching" before coming up to the work.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, April 5.—Medico-Chirurgical Society, Morrisania Medical Society, N. Y. Neurological Society; Pathological Society, Brooklyn.

Tuesday, April 6.—N. Y. Obstetrical Society, East River Medical Assoc., N. Y. Dermatological Soc. "On the Etiology of Infantile Eczema," by Dr. R. W. Taylor.

Thursday, April 8.—N. Y. Laryngological Society, Brooklyn Pathological Section, Jersey City Pathological Society.

Friday, April 9.—Medical Library and Journal Assoc., Harlem Medical Assoc.

Saturday, April 10.—N. Y. Medical and Surgical Society.

SUCCESSFUL MANAGEMENT OF AN
OPIUM HABIT, MORPHIA HYPODER-
MICALLY, OF NEARLY SEVEN
YEARS' DURATION.

By J. B. MATTISON, M.D.,

CHESTER, N. J.

WE appear, once again, before the profession with the closing details of a case of more than ordinary interest, which, on two occasions, has been presented to the fraternity: once* detailing the patient's initial history and proposed plan of therapeutical operations looking to his disenfranchisement from a most debasing servitude of mind and body, and, subsequently,† citing the indifferent success attending our effort, owing, in some measure, to circumstances beyond control.

We have now the pleasure of placing on record the complete success crowning a second endeavor, and as it contains several features of professional interest, and bearing somewhat on the mooted question of sudden or gradual withdrawal, we opine its presentation will not be unacceptable.

Chas. Dimond, whose history as an excessive consumer of morphia hypodermically was narrated through the columns of the *Med. and Surg. Reporter*—vide No. 821—applied to us Dec. 18th, 1873, for relief from the most atrocious attack of tic-douloureux we ever witnessed, utterly defying every remedial measure brought to bear upon it during several days' medication, and which gave way finally, and we hope forever, to a single deep injection of chloroform, after the manner first suggested and practised by Prof. Bartholow, of Cincinnati, and details of which we reported, in full, in this journal for May 1st.

When we first made an attempt at this man's reformation, his average consumption of morphia was grs. v. per diem. After its failure, he returned to the practice of his baneful habit more ardently than ever, soon doubling his former quantity, and when he presented himself with his trifacial trouble it was still larger, his weekly consumption being from one to two drachms, subcutaneously.

Notwithstanding the severity of his neurotic suffering, he expressed a desire to make, once more, an effort towards bursting the bonds that bound him, and, accordingly, passed into our possession his syringe; but the pain being so urgent, such an attempt was not to be entertained for a moment.

For four days subsequently we essayed a variety of treatment looking to his relief, using the morphia in truly heroic doses, reaching as high as five grains at a single injection, with no apparent effect whatever, and only succeeded in putting a quietus upon it by the injection of chloroform, as before mentioned.

This was followed in four minutes by a highly soporific condition, which continued for several hours, during which it occurred to us, could we prescribe anything which would have the effect of prolonging this state we might make a break in upon his opium habit which would prove highly advantageous so far as an attempt at its withdrawal was concerned.

Nothing suggested itself as more likely to accomplish this object than chlor. hyd.; for if it be true, as claimed, that the peculiar hypnotic virtues of this

drug are due to the elimination of chloroform, certainly it would seem to be the most eligible agent under the circumstances, inasmuch as it could but intensify and prolong the action of the chloroform subcutaneously administered.

Accordingly, the patient was directed to bed, and chloral ordered in simple doses every half hour until its soporific properties were decided. Forty grains sufficed to procure a sleep of five hours' duration. The same quantity, dose, and interval as before, was again administered, when he fell into a profound slumber which continued for ten hours.

On awaking he soon became clamorous for his morphia—an interval of nearly forty-eight hours having elapsed since an injection—but as we had determined to ascertain the degree of success attending a second attempt at its withdrawal, his demand was not acceded to; but, in lieu thereof, strychn. sulph. gr. $\frac{1}{4}$ was injected hypodermically, ter die, with the impression on the part of the patient that the injections consisted of morphia in reduced amount, an idea of which, of course, we were exceedingly careful not to disabuse him. The dose of strychnia was given in two injections, for the quantity of liquid injected was an object of prime importance with him, and, as showing the effect of treatment purely psychical, it may be noted that, time and again after giving him his usual allowance, and he was still unsatisfied, an injection of *aqua pura*, clandestinely administered, would exercise, seemingly, a wonderfully potent power for good, and quiet all his clamors, for the time being at least.

Apart from the moral effect of the strychnia injections, the powerful tonic properties of this drug in toning up his nervous system after the prolonged opium debauch, and in eradicating a strongly marked neurotic taint, were brought into play, and, we think, with signally good results.

In addition, we administered subcutaneously, at bedtime, atrop. sulph. gr. $\frac{1}{60}$ to $\frac{1}{30}$, according to the sciatic pain, restlessness, and other varying circumstances of his condition, which yielded effects very satisfactory, and of which we shall speak more in detail hereafter.

Conjoined with this hypodermic medication, patient was placed upon the use of the following prescription:

R. Magnes. sulphas.....	℥ss.
Mangan. "	℥ij.
Fer. "	℥ij.
Quin. "	℥ij.
Acid. sulph. dil.	℥ss.
Aq. ad.	℥viij.

M. S. Tablespoonful in wine-glass of water ter die, and a nourishing diet, beef-tea especially ordered.

To procure sleep chlor. hyd. was prescribed in a minimum dose of gr. xxx., and this quantity pushed gr. x. at a dose, as often as required during the night, until the object aimed at was accomplished.

The above tonic was soon set aside, proving ineligible on account of its bulk, and Wyeth's elix. fer. quin. et strychn. substituted in ℥ij. doses (strychn. gr. $\frac{1}{10}$) thrice daily, continuing strychnia and atropia hypodermically as before.

After using this tonic one week he was ordered:

R. Quin. sulphas	gr. ij.
Tinct. fer. chlor	℥ss.
Liq. potass. arsen.	gtt. x.

M. S. Take at a dose, diluted, after each meal, the other remedies to be continued.

Such was the general plan of treatment pursued—a full nourishing diet, with the most efficient of nerve-tonics hypodermically and per via naturales, and it cul-

* M. and S. R., No. 821.

† Ibid., No. 905.

minated, after a persistent prosecution of *four weeks'* duration, in a consummation as complete and satisfactory as could have been wished for.

Under the above regimen our patient gained strength rapidly; his appetite became actually voracious, and he increased in weight markedly, averaging a fraction less than five pounds per week. No less gratifying was the improved change in his *moral* demeanor; in fact, he seemed to undergo a complete transformation, so that at the expiration of the time mentioned "old things had passed away," and he stood forth a *new* man, thoroughly disenthralled from a most degrading bondage, and fully freed from a physical infirmity which for a three-quarter score of years it had been his painful lot to endure.

A few remarks somewhat in extenso on some points connected with this case may not be altogether devoid of interest. A most decided obstacle to the withdrawal of the morphia was the severe sciatic pain to which the patient had for fifteen years been subject, and which broke out in full fury soon after the relief of his trigeminal disorder. For the removal of this we employed various remedies, all of which failed us until we resorted to vesication of the main nerve involved, applying simultaneously no less than *fourteen* blisters, about three-fourths of an inch square, over the track of the nerve affected, from the point of its emergence to the popliteal space. These were allowed to remain sufficiently long to produce superficial vesication, dressed with *cerat. simp.*, and from that date the sciatic suffering ceased as by magic, and absolutely failed to put in its appearance thereafter.

The rapid and radical relief from the cantharidal application was so notable that it demands more than a passing notice. It confirms fully the observations of Cotugno, Valleix, Anstie, and Stillé, more especially the latter, who declares "sciatica, more than other forms of neuralgia, is rebellious to this and to all forms of treatment; yet it is more amenable to methodical blistering than to any other exclusive method whatever."

Cotugno, first to use cantharides as a counter-irritant for the cure of sciatica, got to himself a wide-spread reputation for the remarkable success attending his treatment, notwithstanding his etiological idea of the disease would scarcely be considered, at this day, correct. Valleix asserts that blisters hold the highest rank in the treatment of neuralgia, and Anstie, in his classical work on this disease, while not admitting them *universally* applicable, insists that they are of the *greatest possible* service in a *large* number of instances, and observes that in sciatica we sometimes "obtain immediate success by two or three repetitions of the flying blister somewhere over the trunk of the nerve." It must not be overlooked, however, that in order to reap this striking benefit the blisters must be "flying." Any action which exercises a depletory effect, under the mistaken idea that the *materies morbi* can thereby be eliminated, will fail of its object; in fact, we should confidently anticipate a distinct aggravation of the sciatic suffering.

Nor must it be forgotten that in the case under consideration the patient had the benefit of what we believe to be the *remedy par excellence* for obstinate cases of sciatica, and we are by no means certain that in the milder cases a similar treatment would not speedily suffice for a cure, viz., strychnia hypodermically administered; and we give it as our confident opinion that the number of cases utterly unyielding will be very limited where a thorough trial of this drug, in gradually increasing quantity until moderate evidences of its toxic properties become apparent, is

resorted to, conjoined with that degree of counter-irritation so strongly indorsed by Valleix, Stillé, Anstie, and others. It may be noted that in this instance the strychnia was continued for four weeks, during one week of which the tri-daily dose was equivalent to one-tenth of a grain before symptoms of strychnism manifested themselves, and then only to a limited extent.

Our patient, ignorant as to the nature of the strychnine injections, was cognizant of the atropia, which was employed with a threefold object—its anodyne property, which, inferior as a rule to morphia, has, nevertheless, a marked power for good—a quality that was appreciated and taken advantage of by our subject.

Secondly, we had previously demonstrated to our entire satisfaction—vide *Reporter*, No. 905—the notable influence of this drug in restraining excessive epidrosial action. In this last instance its reputation in this direction was still further enhanced. The observations of Ringer especially, corroborated recently by Tidd, of Ohio, and others, leave no doubt as to the potency of belladonna, and particularly its alkaloid, in hypercutaneous secretion.

Again, in a previous use of it in this case, we found our patient rapidly relieved from an obstinately torpid intestinal condition, which was to him a source of much discomfort. The same state of affairs a second time presenting itself, the atropia fulfilled our expectation completely, its administration being soon followed by a return to normal evacuations. Trousseau claimed for belladonna the *remedy par excellence* in habitual constipation. He says it does not purge or produce loose stools, but only renders defecation easier. Our experience with it, in the case under observation, was strongly substantiative.

These two valuable properties of this drug, if properly taken advantage of, must largely extend the range of its therapeutical operation. Many pathological conditions will present themselves, in which one or other of them may prove exceedingly beneficial. As to other effects produced by the dose we employed— $\frac{1}{60}$ to $\frac{3}{60}$ gr.—nothing beyond marked faucial dryness and moderate pupillary dilatation was manifested.

No ill results followed the chloral, though it was given in consecutive doses of thirty, forty, fifty, and sixty grains nightly.

Markedly wide is the diversity of opinion among professional men as to the propriety of sudden or gradual withdrawal of the habitual intoxicant in these cases of opium inebriation. In this instance no less an authority than Willard Parker, at whose clinic the man was presented, advised his incarceration and the morphia shut off at once and forever. Sooner than submit to that, the patient repeatedly declared to us he would have committed self-destruction. An attempt of the kind was made by the surgeon of a New York hospital, but it "came to grief," for the man became so violent, smashing windows and the like, that the hospital authorities were glad enough to get rid of him. Corroborative of Prof. P.'s advice, Howe asserts that "'tapering off' will not result in cure."

Opposed to this opinion, among others, is Dr. Parrish, who, as superintendent of an asylum for inebriates, has a fine field for observations, and who declares that he has "no hesitation in expressing an opinion, which has settled into a fixed judgment with me, that for the class of cases with which I have had to do" (and we presume they were by no means unique), "the system of gradual reduction has answered so well that I cannot bring myself to adopt the other plan," and who gives cogent reasons therefor, and fortifies his

statements by citing several cases where this plan has been followed by conspicuously good results.

In an address delivered by him before the "American Association for the Cure of Inebriates," the subject of "Opium Intoxication" is dwelt upon at length, and we refer our readers to a report of the same in the *Medical and Surgical Reporter* for November 15th and 22d, 1873.

Among other deductions from his admirable remarks, are the following:—

"To relieve the symptoms, it is desirable to avoid the shock, as it is desirable to avoid it in surgical operations.

"For this purpose the practitioner should immediately reduce the accustomed supply to the minimum dose which will meet this condition.

"When the minimum is reached, the suffering of the patient begins, and then the practice should be to give tone to the nervous system, as the opium stimulus is withdrawn. The reduction should be in minute quantities, and the tonic doses full and persistent.

"The moral sentiment, the confidence and courage of the patient, should at all times be kept up to the attainable degree.

"Such a course will almost always secure the desired result."

The above we believe to be the plan of treatment best adapted to a large majority of cases. True, we cannot support it from personal experience, by reference to a single case so managed, but it appeals itself (in our judgment) most strongly to "common sense," which is better than any theory, and besides, has the indorsement of those whose *successful* experience entitles them to the very highest respect and belief.

From a superficial view, a plan of treatment directly the reverse of what we advocate answered a perfect purpose in the case under consideration, and, seemingly, our practice was rather inconsistent with our precept. Granted, but there were some unusual circumstances in this instance, which, fully explained, will make it far from inexplicable why we succeeded so well, notwithstanding a complete and immediate withdrawal of the accustomed stimulus.

In the first place, one leading indication under the gradual diminution regime—avoidance of shock—was carried out in a manner similar to its fulfilment in surgical operations, viz., by the production of anæsthesia.

The injection of the chloroform was followed in four minutes by a condition quite akin to that resulting to his moderate inhalation, which condition was prolonged to a greater or less degree, for days, by the free administration of chloral. That by this the man's perception of a desire for his opiate was blunted, we have not the slightest doubt, and this effect being produced in the *early* stages of its withdrawal, when the suffering attending the same was *keenest*, swayed the chances in his favor more heavily than they would have been at any subsequent period.

It must not be inferred, however, when this state of partial anæsthesia was no longer deemed advisable, that the inbreak upon his baneful habit was sufficiently great to enable him to wage the yet remaining battle free from pain. Far from it. On the contrary, he suffered, psychically, to an extent inconceivable save by those "in bonds, as bound with him." But having gotten thus far on his journey towards recovery, and feeling fully assured that if, by any means, he could be enabled to hold out a little longer the goal would be reached, his importunate pleadings were unheeded, and slowly but surely his "*devil*," as he styled the horrible craving, loosed its hold, until, just *twenty-one*

days from the date of his last morphine injection, he shook it off altogether, and stood forth *victor*.

From the foregoing history it may safely be deduced that the opium habit, while throwing about its victims an almost irresistibly seductive influence, is one which *can* be eradicated by a proper course of therapeutical management, and the unhappy victims of this increasing vice restored to their pristine physical and psychological condition. But we reiterate that, in our opinion, this *cannot* best be done by a sudden and sweeping withdrawal of the habitual intoxicant. This course, if it be appreciated by the patient, will be very apt to give rise to a spirit of insubordination quite fatal to the success of the movement, standing, as it inevitably would, in the way of keeping up the courage and co-operation to the desired degree. Conjointly everything necessitating a physical demand for the anodyne properties of the drug, must be thoroughly removed.

Added thereto must be a hygienic circumstance around the unfortunate devotee, aided by medication which will tend most efficiently, in every possible manner, to tone up the shattered nervous system and make amends for the setting aside of the accustomed inebriant.

THE RELATION OF THE GENERAL PRACTITIONER TO THE TREATMENT OF MENTAL DERANGEMENT—OUR ASYLUMS AND THEIR SPHERE.

By EZRA M. HUNT, M.D.,

METUCHEN, N. J.

It is an encouraging omen that two or three of our medical colleges have invited superintendents of asylums to sprinkle in amid the course a few lectures on the subject of mental derangement. Until of late the consideration of insanity was entirely left out in the curriculum of instruction as to medical practice. The young practitioner actually entered upon his profession with demoralized views as to his relation to the disease. He regarded his duty as merely perfunctory. He himself was not responsible for intelligent treatment, but only expected to give opinion as to the need and time for transfer to asylum "for treatment."

Now, whether he will or not, the early treatment of necessity falls upon the average medical practitioner, and not upon institutional experts. A few days, and sometimes weeks, are necessary to determine the degree of insanity, or the need of transfer, or the case itself is gradual in development. Some delay often must occur in arranging change, unless the attack is of the exceptional character of raving mania. Yet so important are these days that they often mark the limit between acute and chronic cases, and determine the ultimate curability of the patient. I have before me the last reports of two asylums in Philadelphia, that of New Jersey, and the very valuable report of the Commissioners of Lunacy for Massachusetts. A reference to what is therein stated, and former knowledge as to prior experiences, emphasize the fact that a large proportion of those that recover do so within one year after admission, and these are largely of not more than three months' previous duration. It is well known that the chances of recovery for cases which have in all lasted over eighteen months are exceedingly limited. Thus, of the 107 patients discharged cured from the Pennsylvania Hospital for the Insane for 1874, 39 were there only three months, 28 between three and six months, 22 between six months and one year, and the remaining 18 are named as over one year, but probably most

of these ranged between one and two years. "If (says Dr. Allen, Mass. Report, 1874) the proper treatment can be applied in its first attack or stage, it is estimated by some that, taking all cases as they arise, from seventy to eighty per cent. can be cured, and others estimate the rate still higher; but if not treated at all, or attempted unsuccessfully, till the disease passes into a chronic state, it is found, as a general rule, that not more than ten per cent. ever recover. This shows the great importance of prompt and early treatment." "The recoveries are confined chiefly to fresh admissions, or to the acute stage of the disease."

"Whenever an individual exhibits marked evidences of derangement of mind, not a day, certainly not a week, should be allowed to pass without carrying him to a hospital." We cannot fully subscribe to the last remark, for there are cases and circumstances which may indicate treatment at home, or less speed in asylum assignment, but surely not a day should be lost in proper medical advice.

And it is just as easy and just as proper that the private physician should be competent to meet, and, in some cases, to continue to treat some cases of invalidity of mind as other forms of invalidity. But the importance of early treatment somewhere cannot be over-estimated. The report of the Friends' Asylum, embracing 1,776 cases, reaching through a series of years, shows 65.91 per cent. of those which were under one year restored, while only 14.57 per cent. of those beyond that period recovered. This so far accords with similar statistics of other hospitals that it is not necessary to multiply proofs of the fact. Probably if the table could be still further analyzed, so as to show not only those of the first year, but the decrease of recoveries in each succeeding month, after treatment was fairly instituted, we would find still more pointedly the value of early treatment. We would carry the idea where it belongs, back into the very beginnings of disturbed mentality or disturbed nerve-function, and say that all experience proves the importance of having the private physician so educated as that the very early treatment of disturbed mentality, which necessarily falls within his purview, shall be so conducted as to prevent the chronicity of the disease. We are finding, more and more, how, in pneumonia, pleurisy, etc., in a very short time the question is decided whether there shall be such deposit resulting as insures tuberculous degeneration, and so in some forms of mental trouble a reflex irritation may leave its early impress on cell-groups, and we get what Seguin calls "retentivity" of abnormal action. This early skilful care is all the more important, because manifold cases of nervous disease and local disorder are so near the boundary line between the sane and insane, that we need to know what the perversion means, and how to deal with it. Not only must all asylum patients pass through the hands of private physicians, but many cases are in fact never sent there, be the accommodations what they may, and others are arrested and cured by a prompt and intelligent meeting of first indications. Says the Massachusetts report: "We have 2,256 in establishments conducted expressly for this class, being but a little more than one-half of the whole number in the State." We have no statistics showing how many cases of threatened derangement are warded off, but we think the experience of physicians records very many in which prompt treatment has proved of saving value.

The physician understanding the laws of mental and functional disorder, and the medical and psychological treatment (or method of dealing) required, will save from going far more patients than he would have oc-

casions to consign to asylums. Says the last report of the New Jersey Asylum: "The symptoms of insanity may consist in any and all variations from the natural expression of the faculties." The treatment has to do with "the correction of any and all physical derangements, as well as of mental and moral disorder." A physician of a leading asylum lately said to us: "I do not recognize any such thing as a mental disease *per se*. Derangement is but a physical phenomenon, dependent upon physical changes or perverted functions of the body." We may vary the old Latin proverb and have an additional truth: "Mens insana in corpore insano." The significance of early physical symptoms, and need and possibility of very early non-expert treatment is shown by another superintendent, who says: "Many or most of the causes that are strongly influential in exciting the disorder, do so through their effect to induce morbid wakefulness. The loss of sleep, therefore, is the real cause of the derangement or unbalanced state of mind; . . . to restore the ability to sleep, therefore, when it is lost, as is often the case with insane patients, is about all that is needful to insure their recovery." An experience in warding off some cases of threatened derangement, and the treatment of some in which the perversion was decided, has impressed upon me the very great importance of the sphere of the private physician in his relation to all mental disorder. Not only in order that he may treat nervous diseases, but in order that he may meet the first motions of insanity, he must be acquainted with the mental and moral relations of the body.

There is need, too, that society be informed on this whole subject. Many of the causes of derangement are within the reach of public and personal lay appreciation. Very many cases consist in a yielding of the will, associated with some physical invalidity, which, if controlled in time, would not get the mastery. There is more room for skilful tact in such cases outside of asylums than in them, and a grander field for the expert in prevention than for the expert in cure. It is often possible so to treat the patient medically and mentally, and so to direct proper exercise of body and of mind as to shake off that misanthropy in which many a case takes its start, or to abate those conditions which are goading the vexed soul into derangement. Even the practicability of change or scene, of treatment away from home and present associations, ought not always to mean an asylum. We are not sure but that the same charity which prompts the erection of asylums should also make the superintending physicians available in consultation to such practitioners as feel their need of counsel, so that some of the cases may be judged of and met earlier at home, or that others which are kept at home may be at the proper time sent to an institution.

In Scotland the Commissioners of Lunacy are required to investigate by visit or inquiry all cases out of institutions, and a similar law prevails in England and Ireland. It is high time that the States and the asylums too did more for the prevention of insanity. There is such a theory as manufacturing material and affording splendid inducements, and such noble charities should not be mere repositories of the sad burden, but should seek to alleviate causes. One of the ways for doing it is for the able and efficient heads of these institutions to do their utmost to instruct other physicians as to their sphere in the inception of the varied forms of the disease. Or may we not aid each other, we by telling what we know of cases in their beginnings, such as they seldom see, and they by telling us of the laws of progress and limitation

afterward, such as are more under their surveillance. Gray, Kirkbride, Brown, and some others, are indeed serving us in this way, but we would stir both superintendents and "lay" physicians to more sturdy correlative and connected work. The field is becoming alarmingly extensive. Pennsylvania, when the Warren Hospital is done, will be able to receive 2,500 patients, and all the room is needed. New York State has large accommodations, and is not behind in material.

New Jersey, with her 655 at Trenton, has found so many unprovided for that she is finishing a mile and a quarter of asylum on Morris Plains. Massachusetts reports 2,256 already provided for, and nearly as many at their homes. The age, too, of inmates is setting back to an earlier decade.

Nervous diseases are multiplying with almost epidemic earnestness, and the pressure of hasty American life is telling upon the coming population. Yet we do not believe there is occasion for visions of increasing craziness, or for any alarm except that which, embracing significant facts, opens the eye to causes and works methodically and intelligently for prevention and cure. The private and institutional physician must join closer in this work. The medical student must study more the nerve department of all disease. The whole profession must realize how wonderfully of late years new and valuable remedies have been found available in morbid conditions. Hopefully and heroically we must join the art of prevention to that of cure, and realize the portentous moment of those first early formative home days of all physico-mental disease, on our dealing with which so much depends the prolongation of the malady, its limitation in a few months, its speedy cure, or its irremediable permanency.

Progress of Medical Science.

ANATOMICAL PROOFS OF TWO BRAIN CENTRES.—Professor Betz, of Kiew, observes that in the cortical portion of the brain there are two tracts lying at the posterior extremity of the sulcus of Rolando and separated by it; the anterior one extends as far as the internal surface of the hemisphere, while the posterior is much larger. In the former of these tracts he has found certain peculiar cell-formations. They are the largest pyramidal cells of the whole nervous system, having a breadth of from 0.05 to 0.06 millimetres and a length of from 0.04 to 0.12 millimetres; they are also provided with a certain number of processes, of which there are two principal and from seven to fifteen accessory ones. One of the principal processes, the larger one, extends to the periphery of the cortex, while the other or thinner one increases in size and is continuous with the axis cylinder. These corpuscles, which he calls *giant pyramids*, are common to men, certain apes and dogs, and they are found at the points where Fritsch and Hitzig performed their well-known experiments. They are found in groups in the anterior cortical tract, but they are sparingly distributed throughout the anterior central convolution, while they are most abundant on the internal surface of the hemisphere. Internally from the fissure of Rolando, the author describes a lobe which he calls the *lobus paracentralis*, and which he regards as a *motor* tract that is identical in men and other animals. In the former it lies concealed in the middle of the hemisphere, while in the latter it is free.

In the posterior cortical tract the author describes large corpuscles with few processes, without a sharply defined axis cylinder, and having a thin peripheral process unprovided with lateral branches. This tract he regards as *sensory*. To the former of these two tracts especially he looks for interesting discoveries elucidating the subject of central paralysis, epilepsy, eclampsia, hysteria, and aphasia.—*Med. Central-Bl.*, xii., 37, 38, 1874.—*Schmidt's Jahrb.*, 1875.

FORCIPRESSURE.—At a recent meeting of the Société de Chirurgie of Paris, M. Verneuil called attention to the value of the use of forceps in compressing bleeding vessels, and he gave the name of *forcipressure* to the method, which, however, he did not claim as new. He stated that he was in the habit of applying the forceps in this way when the hemorrhage was severe and from a large extent of surface. The instruments might often be left in place for several days.

M. Péan has also made some contributions to the same subject. In a recent communication to the Academy he states that the application of forceps for the arrest of hemorrhage was indicated in the following three cases:

1. To prevent hemorrhage, by compressing the vessels before the incisions were made. This procedure was especially useful when peritoneal adhesions were to be cut through.
2. To arrest hemorrhage temporarily, as in the course of an operation, using the ligature subsequently, if the vessels bled.
3. To arrest hemorrhage definitively; he then applied them and left them in place with the dressings. They were removed on the first, second, third, or fourth day.

The forceps he used were very much like the ordinary dressing forceps, and the jaws were either T-shaped, diamond-shaped, or triangular. An ordinary rack and pinion attachment was fitted to the handles, and in this way firm compression could be maintained indefinitely. M. Péan had used these forceps in the operation of castration, when he found it desirable to compress the cord. He applied two of them to the cord, removing them on the fourth day.—*Journ. de Méd. et de Chir.*, March, 1875.

ON NERVES CONTROLLING THE DILATATION OF VESSELS.—Professor Goltz and others have been making experiments on dogs to determine the effect on the temperature that followed the section of nerves. They found that after dividing the sciatic the vessels in the affected limb underwent active dilatation, and this result occurred repeatedly in the same limb, if only section were again made of the nerve at a point nearer the periphery. As a result of these experiments, Goltz maintains that on section of a nerve the *vaso-dilator* fibres contained in it are irritated, and in consequence produce an active dilatation, which, however, exhausts itself subsequently and is followed by a persistent contraction. It is believed further that the tone of the vessels is maintained by certain nerve-centres which exist in the vascular walls. These views are believed to derive support from the fact that they explain certain observed phenomena, as, e.g., that the penis of the horse becomes erect after section of the pudic nerve, the vessels of the belly dilate after division of the splanchnic, hyperæmia of the eye follows section of the trigeminus, etc. The author also claims that the condition of irritation, which is constantly observed in the sensitive nerves after section, supports his hypothesis, e.g., the pain in the fingers, after division of the median nerve.—*Med. Central-Bl.*, xii., 41, 1874.—*Schmidt's Jahrb.*

A SIMPLE PROCESS FOR ESTIMATING UREA IN THE URINE.—Messrs. W. J. Russell and Samuel West give the following description of their method: The reagent employed is a solution of hypobromite of soda in considerable excess of caustic soda; and the most convenient strength of solution is found to be that prepared by dissolving 100 grammes ($3\frac{1}{2}$ oz.) of caustic soda in 250 c. c. (9 oz.) of water, and adding to this, when cold, 25 c. c. (7 drachms) of bromine. The solution unfortunately decomposes if kept for some little time, and it is safer to make it in small quantities as it is required. This may be easily done by keeping in stock the solution of caustic soda, and adding to a portion of this the requisite quantity of bromine at the time the experiment is made. The apparatus, the form of which is shown in the accompanying sketch, consists essentially of three parts: a tube, A, in which the reaction takes place; a measuring tube, F, to collect the gas produced; and a small pneumatic trough, CD.

The tube, A, about nine inches long, is narrowed two inches from the closed end, and a bulb, B, holding about 12 c. c., blown on it. The upper part of the tube contains about 25 c. c. This is fitted, by means of an india-rubber cork, into the small elliptic tin trough, CD, about three inches long, standing upon three legs. In using the apparatus, a 5 c. c. pipette is filled with the urine, and the liquid is allowed to flow into the bulb of this tube. Water is added, thus washing down the urine which adheres to the sides of the tube, and filling the bulb up to the point of the constriction. A glass rod, with a piece of india-rubber tubing about half an inch long drawn over the end of it, is then introduced, so that the india-rubber plugs up the constriction. The hypobromite solution is then poured into the upper part of the tube until it is full, and the trough is afterwards half filled with ordinary water. The graduated tube, F, is filled with water, the thumb placed on the open end, and the tube is inverted in the trough. The glass rod is then pulled out, and the graduated tube is slipped over the mouth of the bulb-tube. The reaction commences immediately, and a torrent of gas rises into the measuring tube. With the strength of the hypobromite solution which is suggested, the reaction is complete in the cold in about ten or fifteen minutes; but in order to expedite it, the bulb is slightly warmed. This causes the mixing to take place more rapidly, and the reaction is then com-

plete in five minutes. The reaction will be rapid and complete only when there is considerable excess of the hypobromite present. After the reaction the liquid should still have the characteristic color of the hypobromite solution. The simplest means of supporting the measuring tube is to have the bulb-tube corked into a well, G, which projects from the bottom of the trough, about one inch downwards. The graduated tube stands over the bulb-tube, is supported by it, and rests upon the cork in the bottom of the well.

It is convenient to have at the other end of the trough another well, H, which will form a support for the measuring tube when not in use. The gas collected is nitrogen saturated with aqueous vapor, and the bulk will obviously be more or less affected by temperature and pressure. It has hitherto been necessary to make correction by calculations of some intricacy for the variations in the bulk of gas which these produce, but with the present form of apparatus it is found that these corrections may be avoided, and the volume of gas read off at once without calculation.

The reason of this is the following: When urea is decomposed by hypobromous acid, the whole of the nitrogen is not given off, but there is a loss of 8 per cent. at 60° Fahr., which is about the ordinary temperature of wards; however, the increase in the bulk of gas caused by the temperature, moisture, and pressure, amount exactly to 8 per cent.; that is to say, the increase due to these causes exactly equals the loss of nitrogen due to the incomplete decomposition. In other words, if we make no correction at all we get exactly the quantity of gas we ought to have. Hence all calculations are avoided. The measuring tube has upon it the figures I, II, III. These mean 1, 2, 3 grammes of urea in 100 c. c. of urine; *i. e.*, 1, 2, 3 per cent., as it may be called; so that if after experiment the level of the gas stands opposite II. on the tube, the urine experimented upon contains two per cent. of urea. Sugar does not interfere with the reaction and albumen only so far that the bubbles take a long time to subside. It is advisable, therefore, to remove the albumen by boiling quickly with a few drops of acetic acid, and to filter. Five c. c. of the filtrate is then taken and estimated as above.—*The Practitioner*, February, 1875.

DIVIDED TENDO ACHILLIS.—Dr. Pierson, of Augusta, Ill., writes that the cases of divided tendo achillis, recently reported in THE RECORD, call to mind a case he was called to treat some twenty-five years ago. Two young men were chopping on the same log, on opposite sides, and near each other; the one losing his balance, threw up one foot to secure it, but just in time to meet his brother's descending axe, which cut directly across and divided the tendo achillis about one and a half inches above its attachment to the os calcis. He was absent from home, and did not return for several days after the occurrence, when it was dressed by a neighboring physician by simply stitching the skin together and bandaging. When the Dr. saw the patient the stitches had torn out, and the wound was suppurating freely, gaping wide open, showing both ends of the tendon fully an inch apart. He could only bring them together by the stitches after flexing the foot back to its utmost; by keeping it in that position, and under the use of adhesive straps, the wound healed, and contrary to all expectations, the patient soon had the full and free use of that foot, though for a time he was somewhat lame. The patient continued to reside in the vicinity, and now for a number of years has walked without apparent lameness. This case is another exemplification of the fact that union of tendons by suture is a good operative procedure.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

SPECIALISM AND GENERAL MEDICINE.

During the past month there has been a large accession to our ranks. We are informed that never before have our leading medical schools graduated a larger number. Whether there is such an absolute need for physicians as to call for this abundant supply, will be a question which will doubtless be answered in far from a satisfactory light by the majority of aspirants now waiting for business. We have very little doubt that the majority of the graduates have determined to espouse a specialty. This could hardly be otherwise, considering the conventional understanding regarding the position and emoluments of specialists in general. It is now very generally believed that not to be a specialist is to be nothing. This conviction has forced itself upon the professional mind by the great success with which some specialists have met, not only in the way of reputation, but of pecuniary gains; by the established position which specialism has made for itself against very many and very powerful obstacles; by the progress which it has insured to medicine in enlarging our means of observation and making more sure our methods of treatment. A few years ago specialism was considered but another name for quackery; now, sentiment has so far changed that every successful specialist is envied. As is often the case, we have gone from one extreme to the other. The proper course is somewhere between the two. The young medical man who is about to start upon his professional career should understand where this medium lies.

To such as are determined to be specialists, we would say, in the first place, do not be in any hurry. To be a good specialist requires a great deal of time, study, and patience. When one has earned such a reputation by such means, he is certainly to be envied. We have always held that no one could be a successful specialist unless he had first been a successful general practitioner; that a special and thorough knowledge of the

diseases of any one organ was as natural an outgrowth of general knowledge of medicine as was the branch from the parent trunk. This is a point which younger men are very apt to lose sight of in their eagerness for what they believe to be professional success. If every one would fully appreciate the importance of thus developing a specialty, we should be able to draw the distinction between mere ambition and real merit, to learn the difference between the mushroom upstart and the plant of slower and steadier maturity. The truism that all good things come slowly, is particularly applicable to the growth of a specialty.

Even when we take all these conditions into account, and make every endeavor to fulfil them, it may be well to inquire if we are not in danger of crowding the ranks of specialism. Considering the great number of those who have already entered the lists, there is a pertinency in the question which should not be lost sight of. The specialists themselves have been ready to acknowledge this long ago, but we consider that the time has come for the raw recruits to view the situation with calm consideration. Every organ is now so well attended, that it is almost next to impossible to find room for any newcomers. It would seem to be necessary to start some new specialty, to settle upon some of the more obscure organs, and subject them to the penalty of greatness. We have no doubt that this emergency will be properly met in time. We have always been in favor of the study of specialties, when that study was properly carried out; but there is no necessity of drifting into one-ideaism on the subject. We should not forget that general medicine has its claims also, that to be a general practitioner, pure and simple, should also be the object of our high ambition.

By properly allowing the claims of this class of professional men, we take another very legitimate means of tempering the fashionable excitement for specialism which has taken so much possession of the professional mind. There is more danger at present of having too many specialists than too many good general practitioners. We ask our younger brethren to consider this fact. General practice offers to-day as many inducements for the thorough student as any of the specialties. Even in a pecuniary point of view it will, in the long run, compare favorably with the best of them. The majority of physicians who have accumulated a competency have done it in general practice alone. The relation which the general practitioner holds to the community is an enviable one in every sense, his influence is widespread, and his services are a necessity to all. His position is a thoroughly independent one, being always sure of employment, whether in a crowded city or in a remote rural district.

If the young man desires to be a specialist, he should of necessity prepare himself for that office by general practice, and if he succeeds in that, as indeed he must if he be a faithful worker, he will be giving services which will always be in demand, and for which

he will always be well remunerated. If at the present time many of the young men who are about going abroad to study a specialty, would accept this fact, both themselves and the community at large would be the gainers thereby. There is always a need for a general practitioner, and the young man who resolves to qualify himself for the duties of that office can consider his success certain, and his ultimate competency assured. Common-sense is, after all, the best specialty in medicine, as it comprises a wider range of subjects than any other, and is a field which, on account of the neglect of general practice, needs a great deal of cultivation. If we wished to assure the success of the greatest number of our young men looking around for opportunities, we believe we could give them no more wholesome advice than to be general practitioners.

THE EARLY TREATMENT OF THE INSANE.

THE paper of Dr. Hunt in another column, advocating the necessity of a knowledge of the various forms of insanity, is timely and suggestive. That the necessary means to such an end is the establishment of chairs of psychology in our medical colleges cannot be questioned. Such a plan has been repeatedly urged in these columns, and we are pleased to have an opportunity to urge its practicability once more. The facts which he presents regarding the utility of the measure, although confined to a somewhat limited examination of asylum statistics, can find a parallel in a more extended observation.

It is now a well-established principle in the treatment of the insane that while the acute cases are quite curable, the chronic cases are very intractable. The general practitioner cannot too soon appreciate the force of this fact, not only in the interest of the patient, who may be irreparably lost, but in that of the asylums, which are now so crowded with incurables. While we admit that the treatment of diseases of the mind is a distinct specialty, we must also be prepared to offer our advice in many ordinary cases which constantly arise in the every-day practice of the family physician, and, as in all other diseases of a special class, have a sufficient knowledge of it to be able to decide when a given case must be resigned into the hands of an expert. The principle advocated in the paper in question is a sound one, and commends itself to the serious attention of every one liable to meet with the cases to which it refers.

THE KINGS CO. MEDICAL SOCIETY AND THE EDUCATION OF THE PUBLIC.

THE report of the Committee of the Kings County Medical Society concerning the propriety of giving the necessary information to the public on medical topics is one of considerable interest to the profession. The position assumed, although a radical one, deserves commendation, especially at this time, when newspaper

advertising is so extensively practised. There is no question that the public are in want of the kind of information which can only be furnished by well-educated physicians, and that if this information is given in a proper way it will be respected by those for whom it is intended. The precise way to accomplish our mission as medical teachers is, however, not so easy to determine. The proposed plan has the recommendation of novelty, and for this reason is entitled to a fair trial. This is, after all, the best test of its practicability. If the experiment be a failure the profession stand ready to credit the Society for good intentions and sympathize with it in the laudable endeavor to solve a very difficult problem. We earnestly hope that success will crown the effort.

Reports of Societies.

NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

Stated Meeting, March 15, 1875.

THE PRESIDENT, DR. MEREDITH CLYMER, in the Chair.

PARTIAL PARALYSIS AND WANT OF CO-ORDINATION FROM IRRITATION OF THE GENITAL ORGANS.

IN the issue of THE RECORD of March 6, 1875, is found an abstract of a paper read before the Society upon "Partial Paralysis and Want of Co-ordination from Irritation of the Genital Organs," by Dr. Lewis A. Sayre. This question was made the special order for discussion at the next regular meeting of the Society, held March 15, 1875.

DR. OTIS opened the discussion. He remarked that he was happy to have the opportunity of confirming the observations made by Dr. Sayre upon this class of cases, by a somewhat extended experience of his own. The trouble in those cases which Dr. Sayre has referred to seems to have involved only the prepuce, and that only at its reflection from the glans. In his own experience those irritations that have produced reflex troubles and partial paralysis, have not been confined to this particular region. A little more than one year ago he read a paper before the Academy of Medicine, in which he gave a *résumé* of twenty cases where reflex irritation had resulted from strictures in the anterior portion of the urethral canal.

With regard, however, to paralysis arising from preputial irritation, he had had some extraordinary experience. He referred to the following cases:

CASE I.—A child came under his observation who was suffering from retention of urine. Upon examination it was found that the preputial orifice was almost closed. No instrument was at hand sufficiently small to enable him to relieve the retention. With a narrow bistoury he slit up the prepuce, and went to his office for an instrument of the proper size with which to draw off the urine. When he returned, the child had passed water several times during his absence, and subsequently was not troubled with retention. It was represented by the parents that before the operation the child was not able to sit erect like other children; but that there seemed to be a condition of partial paralysis that was general. All that paralysis passed

off in a very short time, within two or three weeks, and the child made a complete recovery.

CASE II.—This was another child who had been under observation for several years. He was badly nourished, of scrofulous parents, and was supposed to have a scrofulous cachexia. His mental condition seemed to be obtuse; he took no interest in the sports of the other children, and he could not be induced to leave his mother at all; he was restless, and apparently uncomfortable, and suffered severely from headache. Dr. Fordyce Barker saw the case with him in consultation, and a plan of treatment was decided upon, but no benefit followed. One of the inconveniences the child suffered from was a very troublesome enuresis. He wet his bed very frequently, and wet his clothing daily. Belladonna and various remedies had been administered, but without permanent benefit. Upon examining the penis a redundant and contracted prepuce was found. This was removed, and when removed it was found that the prepuce was adherent to a considerable extent over the glans. The *meatus urinarius* had been subjected to inflammation, extending to it from the prepuce, and this was also contracted to a considerably small orifice. The opening was increased in size up to the normal calibre of the urethra, and the patient left for the day. Upon calling the next morning he found that this boy had not made water since the operation, nor was there any evidence that there was any over-amount in the bladder. From that time forward he had no trouble with his enuresis. His father sent word the following day that his boy seemed entirely changed in his appearance and actions. Formerly, his eye had had the same expression as the eye of a fish, but that since the operation this expression had changed, and he immediately began to play with the other children. The change was so marked, and followed the operation so quickly, that it must be attributed to the relief afforded by the operation.

Improvement steadily followed. The boy gained flesh very rapidly, and continued in this manner for several months, when he again began to be troubled a little with the enuresis. Upon making examination, contraction of the preputial orifice was again found, and it was redivided. Since that time he has had no trouble whatever, and has completely recovered.

Dr. Otis then read letters from Dr. Mastin, of Mobile, and Dr. Francis Brown, of Boston, in which the history of cases was related equally as striking as any he had seen or had been reported by Dr. Sayre.

Dr. Otis continued by saying that he believed that the influences of irritation, which are oftentimes reflected irritations of this kind, extend throughout the genito-urinary tract, and throughout the entire sympathetic nervous system. To show how remote the effects of irritation of this kind may be, he related the case of a physician who came to him some four months ago from Ohio, suffering from urethral stricture. He had five strictures between the external opening and the bulbo-membranous junction, and they were all divided at one sitting. They would admit a bulbous sound of only No. 19, French scale, before the operation. They were divided to admit No. 34, French scale.

Two days after the operation, he (the patient) remarked that perhaps he was foolish, but that there were some little matters that had troubled him before the operation which had entirely disappeared since. For instance, he had suffered from pain about the lower part of the spinal column and about the groins, which prevented him from stooping. Since the operation, however, all that feeling had left him, and he felt nothing of it subsequently. He had also noticed

that within the last year, while sitting with a book in his hand and reading, that the book would suddenly fall from his hands; and he became alarmed, thinking that he was probably to have an attack of paralysis. This occurrence was occasionally repeated, and he had occasional attacks of paralysis of the terminal phalanx of the index finger, particularly upon exposure to cold; but he had worked himself up to the belief that all these symptoms were due to fatigue, etc. All these symptoms, he said, had entirely disappeared since the operation, and had not returned, although exposed to cold and the same influences that he had formerly supposed to be the cause of them. There was another thing, he said, which was exceedingly annoying, and that was a constant *ticking* in his head. That annoyance also disappeared after the operation, and the patient was confident that all these symptoms had been relieved by relieving the irritation in the urethral canal. When we look over all the cases which have been reported, says Dr. Otis, we must recognize in them an affection of the spinal cord, and it is not too much to suppose that irritations at different points in the genito-urinary apparatus, which is so intimately connected with the whole sympathetic nervous system, may originate in the cord itself, and be transmitted to any part of the body. We have irritations transmitted from the neck of the bladder to the end of the penis, and from the end of the penis to the neck of the bladder, and an *unfelt* irritation at the neck of the bladder will give pain at the end of the penis.

He then related a case in which the patient had spasms at the neck of the bladder for five years, and suffered the most intense agony, agony which at times was terrible. A few days before his death he suffered for the first time from irritation at the end of the penis, so severe that it seemed perfectly unendurable. In his agony, and seeking something for relief, he applied snow to the end of the penis, and it gave relief from the spasm at the neck of the bladder *at once*. During the remainder of his life he derived great comfort from this accidentally discovered plan of treatment.

He was of the opinion that the class of irritations under consideration is very common; and even when no phimosis or stricture is suspected, that upon examination such conditions will be found as are capable of producing just such effects as have been mentioned.

DR. CARROLL remarked that his attention had been called to the condition of the prepuce and glans penis in healthy children, and that he had found in nearly every instance adhesions between the two surfaces. He had had a case under observation for some time, and had found that these adhesions little by little had given way, showing that in many cases, at least, adhesion is physiological in early life. He believed that it was well to take this fact into consideration, while watching the class of cases alluded to.

DR. OTIS remarked that there are very many of these preputial adhesions that are pathological, and not physiological. He was of the opinion that the remarks of Dr. Carroll would lead gentlemen astray in attributing these results to physiological processes. For it very frequently requires considerable force to separate the adhesions that are found, and he believed that all attachments which merit the name of adhesions are pathological, and the patients do not get well of themselves. There are cases, doubtless, which may fall under the class included in Dr. Carroll's statement; but in the majority of cases the union between the prepuce and glans was pathological, and not physiological.

DR. EMERSON inquired of Dr. Otis at what age he would regard the union which is found to be pathological, and not physiological?

DR. OTIS answered, at any age in which there was such a condition of the parts as would not allow of separation without hemorrhage. The normal agglutination of the parts is not an adhesion, strictly speaking. Any adhesion which is worthy of the name is pathological.

DR. CARROLL remarked that in speaking of adhesions he did not mean adhesion which is simply an agglutination. The theory which he advanced was simply this: In early infancy there is first formed a very small furrow at the base of the glans, and from this the lining membrane of the prepuce is reflected over it. At first this furrow is very small, but with the gradual development of the child the entire reflection is deepened, and yet the two surfaces remain in contact by agglutination. The few cases, however, which had fallen under his observation might not warrant these conclusions.

DR. ROBERT NEWMAN related a case in which the boy had constant spasmodic trouble from genital irritation. The prepuce was long, and adhesions were present between it and the glans. Circumcision was suggested, and objected to by the parents.

He endeavored to separate the adhesions by other means, and was able to do so only by repeated attempts. Separation was finally completed, the prepuce retracted, and the boy made a complete recovery.

He had not found such a physiological condition as described by Dr. Carroll, and was of the opinion that the adhesion found was pathological and not physiological.

It was further of the opinion that the condition that produced the results referred to—spinal irritation, partial paralysis, etc.—was not simply an elongation of the prepuce but an elongation combined with a narrowing of the preputial opening. Perhaps these two conditions go together. Perhaps the long prepuce may retain small quantities of the urine, and the residuum gives rise to the adhesions, and the pathological condition may be explained in this manner in part. He also mentioned divulsion as an operation that in many cases may answer the same purpose as circumcision.

DR. OTIS related a case, touching upon the matter of agglutination, in which the man, twenty-four years of age, had never been able to retract the prepuce over the head of the penis, on account of the attachments that were present between the two surfaces.

Being engaged to be married, the man thought that something should be done in the way of repair, and set himself to work. He finally succeeded in uncovering the head of the penis without producing hemorrhage. This case goes to show that the union in some cases is not very firm, and may be broken up perhaps without trouble.

DR. SAYRE remarked, that it mattered not whether the two surfaces are agglutinated pathologically or physiologically, the condition developed was one in which it was impossible for the prepuce to unfold itself and permit of the exposure of the head of the penis, and the parts sooner or later became thickened, hard, and indurated, and it is impossible to separate the surfaces without an operation. The doctor also mentioned one or two cases.

DR. EMERSON mentioned the case of a young lad, ruddy and intellectual, who became troubled with peculiar symptoms. For instance, while performing examples upon the black-board, at school, he would suddenly be seized with mental aberration, which for a time blotted out his reasoning faculties, a sexual in-

pulse would come over him, and a small quantity of semen would escape. His health broke down in consequence. Upon examination it was found that he had never been able to retract the prepuce over the glans penis. Circumcision was performed, and a hardened mass of smegma removed from about the corona. Improvement followed the operation immediately, and all the impulses and mental impressions entirely disappeared. He was over twenty years of age when he was relieved of the trouble.

DR. OTIS further related a case in which the diagnosis of cerebral softening had been made by that acute observer Dr. Brown-Séguard. But as the patient was going out of his office, Dr. Brown-Séguard noticed an unsteady gait and stumbling that brought to his mind the possibility of genital irritation. The patient was called back, an examination made, a contracted preputial orifice found, balanitis, etc. This condition was looked upon as a possible cause of the trouble. Circumcision was performed, and within six weeks the patient was entirely well.

DR. CLYMER remarked that fully one-third of the cases of nervous diseases he was called upon to treat were dependent upon some form of genital irritation; and that the other two-thirds were due to blood-poisoning, either syphilitic, malarial, or lithæmic.

The Society went into executive session.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, March 22, 1875.

THE PRESIDENT, DR. H. B. SANDS, in the Chair.

TUBERCULOSIS.

DR. CARL HEITZMANN read a paper upon the above subject of which the following is a brief abstract: He first considered the history of his subject, and stated that the true pathology of the affection dates back to only about one hundred years ago; although in the seventeenth century physicians observed various nodules in the lungs which were called tubercles, the same as they are to-day. Following this was a brief reference to the doctrines concerning the origin of tubercle that had been announced from the time of Bayle and Laennec up to the present date. Bayle and Laennec denied that it ever had an inflammatory origin. Broussais promulgated a theory directly opposed to this, namely, that tuberculosis of the lungs was nothing more than chronic pneumonia.

Louis supported the theory of Laennec. Carswell, Clark and Stokes regarded some cases as terminations of catarrh. Virchow limited the term tubercle to miliary, and suggested the term cheesy for the term infiltrated. Miliary tubercle is a hyperplastic formation and has to do with the lymphatics. The views of Virchow were used by Niemeyer, and he states that every pneumonia, especially that styled chronic catarrhal, may terminate in consumption, while miliary tuberculosis only follows ulcerative pneumonia.

Reference was also made to Dr. Austin Flint, who opposes the teachings of Niemeyer, and also to the fact, that, since 1865, tuberculosis has been pronounced to be a disease that can be produced by inoculation. Indeed, the controversy upon this point is still going on. The doctor then proceeded to state the results of his own observations, derived from the careful examination of more than 300 bodies in which tubercles had been found after death. His remarks were confined to tubercle of the lungs, and he classed his cases under four distinct heads.

1. *Chronic Tuberculosis*.—This could more properly be called localized tuberculosis, for it is found chiefly at the apices of the lungs. This is the form of the disease frequently found in the anatomical room, and of itself rarely proves fatal. The changes that are found in such lungs are in the form of nodes or infiltrations, sometimes nodules, and are the result of healing processes.

2. *Subacute Tuberculosis*.—To this class those cases belong in which there are disseminated tubercles or formation of new tuberculous nodules in a relatively short period of time.

3. *Tuberculous Pneumonia*.—This form of the disease commences not infrequently in the lower lobes of the lungs after capital operations, and the first manifestations of pathological changes are ordinarily in the region of the smaller bronchi.

4. *Acute Miliary Tuberculosis*.—In this form of the disease both lungs are almost always affected to the same extent, and the same kind of deposit is also found in the meninges of the brain, liver, peritoneum, etc. It always terminates fatally after the development of typhoid symptoms, and in ten per cent. of the cases no cheesy change can be found after death. With regard to the nature of tubercle, as to what it is, and what its essential signs are, his conclusions were that it is not evidenced by the presence of nodules (for nodules are found in the body under a variety of conditions); that it is not proven by the presence of infiltrations (for infiltrations non-tubercular in character are found everywhere in the body); nor yet that it is the presence of cheesy metamorphosis, for this also occurs independent of tuberculosis. Still, further, the presence of hyperplastic formations cannot be regarded as characteristic of tuberculosis, but he believed that tubercle is the product of inflammation, and arises only in such tissues as have blood-vessels. In other words, it is a new tissue, composed of small elements, small nuclei and nucleoli, is destitute of blood-vessels, and is developed out of inflammation. It becomes cheesy through lack of vitality, and suppuration of the mass is always the result of changes occurring in the adjacent tissue of an inflammatory character. The treatment of tuberculosis mentioned was that already given by Virchow, namely, to remove the predisposing causes, and avoid all noxious influences. The paper was then received by the Society, and became the subject for discussion.

DR. DELAFIELD remarked that the historical sketch with which the paper was prefaced seemed quite sufficient to show that the question of tubercle was far from being settled. Since the time of Bayle and Laënnec these questions have been discussed, namely, what is the relationship between serofula and tuberculosis? what is the relationship between acute miliary tuberculosis and chronic tuberculosis? and what is the relationship between tubercular disease and chronic inflammation of the lung?

As regards these questions, medical opinion has been constantly setting in different directions.

After having followed Virchow's theories for some time, there is now an apparent tendency among observers to hasten and arrange themselves upon the other side, and to return to the old theory that all phthisis is tubercular. The doctor mentioned Rindfleisch as being one of the ablest advocates of this theory, and referred to the treatise he has published in Ziemssen's *Cyclopaedia* as a paper which, when translated into English, will doubtless attract numerous followers. The style of this author is so attractive, his statements are so bold and definite, and the successive steps in the process are given with such pre-

cision and accuracy, that the theory he advances can hardly fail to draw many in the direction of regarding serofula and tuberculosis as one and the same thing; also that acute and chronic tuberculosis are identical in nature; and still farther, that all phthisis is tubercular phthisis.

Rindfleisch states that there are specific tubercular corpuscles; and that the precise position at which tubercle is always first developed is exactly where the smallest bronchi join with the interlobular passages.

The personal opinion of Dr. Delafield, however, was that the forms of phthisis which he had seen in New York were not such as to allow him to support the theory advanced by Rindfleisch.

For of serofula, as it is known in Germany and France, but little, comparatively speaking, is seen in this city. A moderate number of cases of acute tuberculosis is seen among adults, and of chronic phthisis a great deal is seen; but the forms of chronic disease of the lungs which occur here seemed to him to present, certainly in a very marked degree, such lesions as are most commonly arranged under the head of chronic inflammation.

He was not able to see any more reason for calling such a chronic inflammation by a specific name, such as tubercular, etc., than for designating a chronic inflammation of the liver or kidneys by some particular term; for in chronic inflammation of the lungs, or phthisis, we have the same products as when the same process occurs elsewhere, except as it is modified by the characteristics of the organ in which it takes place. Of course it was impossible for him to enter upon an extended discussion, and give his reasons there why he held to this opinion; and he was also very far from saying that he felt obliged to always hold to such a belief, for our knowledge upon the subject is too steadily increasing to warrant permanent adherence to any definite theory.

The type of the disease, however, that had most commonly been seen by him had presented characteristics which were of a definite inflammatory nature, and these were in the way of production of fibrous tissue in the lung. His opinion was that the most common form of phthisis seen here is that in which there is no great amount of cheesy matter in the lung, but that in which there is a large amount of new connective tissue formed together with a marked amount of chronic inflammation of the pleura and bronchi. In other words, the condition found belongs more to what has been called, by some English writers, cirrhosis of the lung than any other.

DR. ELSBERG inquired of Dr. Heitzmann whether his views coincided with those of Rindfleisch or not, for it had appeared to him that they were directly opposed to the views of that author? He wished also to propound another question, and that was, why not place the form of the disease named by Dr. Heitzmann, "tubercular pneumonia," under the head of "subacute tuberculosis"?

DR. HEITZMANN replied that his reasons for naming one form of the disease "tubercular pneumonia," was because the symptoms of true pneumonia were very much more prominent in this than in the second class of cases, which he had called *subacute*.

It is true that cases occur in which the dividing line is almost nothing, but those are exceptional to the general rule; for all the symptoms of inflammation in a healthy tissue are very apt to be developed in those patients whom he had included in the third class. He further stated that he coincided with the remarks made by Dr. Delafield.

DR. DELAFIELD remarked that he did not wish to be

understood as saying that the views advanced by Dr. Heitzmann and those held by Rindfleisch are identical, but simply that he thought the observations of both had a tendency to lead us in the same direction.

Dr. JACOBI remarked that if we should retrace our steps, and finally come to conclude that the doctrine announced by Laennec, holding that all phthisis is tubercular, is true, it would not be the same statement as that made by Laennec, for physiological and pathological study have advanced very much since that date. He certainly was glad to see the apparent retrograde movement, and will be pleased to learn that it finally turns out to be in reality what it now is in appearance. He fully agreed with Dr. Delafield in the belief that the larger number of cases of phthisis seen here are not tubercular.

What is called scrofula is not found in this country as it is in Europe, and this may account for the occurrence among us of a larger number of diseases which are inflammatory, and not scrofulous or tubercular in character.

There is a special tendency to cell degeneration and cheesy metamorphosis in those who have a poor circulation, and the fact, as it appeared to him, that circulation is better in this country than in Europe, accounts for the smaller number of cases of tuberculosis in later life than is seen there. It may be that our observations are just as correct as those made in Europe, and finally it may be determined that the observations made in both countries lead to the fact that tubercle is not of inflammatory origin, and on the other hand that phthisis is not necessarily tuberculosis.

The subject was further discussed by Drs. J. C. Peters, Elsberg, Jacobi, and Heitzmann.

Under the head of Miscellaneous Business, Dr. O'Sullivan presented a resolution providing for the formation of a committee by the Society upon *Public Education*.

The resolution was referred to the Comitia Minora.

There being no further business, the Society adjourned.

MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

REPORT UPON OBSTETRICS, BY MATTHEW D. MANN, M.D.

In the absence of the President, Dr. Loring occupied the chair. The last meeting of each month held by the Association is devoted to a report upon some medical subject, in which it is expected that all the important operations, peculiarities in treatment, etc., touching upon the subject under consideration, will be brought forward.

In the *résumé* given upon Obstetrics, at the last meeting in the month of March, Dr. MANN noted many items which are of practical importance to the accoucheur, and a share of these have already been mentioned in the columns of THE RECORD within the past year. A few items, however, may be mentioned, without incurring the risk of needless repetition.

Puerperal State.—Quite an innovation upon the usual management of woman after confinement has been suggested by Dr. Goodell, of Philadelphia. His suggestions are based upon hospital experience, and are that the time-honored dose of physic administered the second or third day should be abandoned; that what has been termed milk fever, occurring about the third day, is a *myth*; that the woman should be fed well from the date of her confinement; that requiring the patient to remain in bed more than five days, as a rule, is unnecessary and

not beneficial, but, on the contrary, if the patient is permitted to slip into a chair at the end of the fifth day, her position is more favorable for a complete discharge of the lochia, and in this manner we secure the best deodorizer that can be employed. In addition, the change of position favors the process of involution, and the slight amount of exercise which the woman gets in this way conduces greatly to her speedy and perfect recovery. He disapproves of the use of the binder for more than a day or two, because it interferes with the action of the abdominal muscles, consequently retards restoration to the previously normal condition.

Vomiting of Pregnancy.—Several cases have been reported in which injections of hydrate of chloral have proved of the greatest service in controlling this symptom.

Induction of Premature Labor.—The statistics upon a large number of cases were brought forward to prove that this operation may be followed by good results, and is not to be dreaded by the obstetrician.

Thermometry in Pregnancy.—The thermometer has been proven to be a valuable instrument for determining whether pregnancy is present or not. The temperature of the uterus, when impregnated, as found by introducing the instrument into the cervix, is higher than that of the vagina.

The question was raised by Dr. Foster, whether there might not be danger of producing abortion by this procedure?

Sore Nipples.—Anything that may be suggested for the relief of this distressing complaint is usually hailed with delight. The proposition has been made that if two conditions can be fulfilled, the nipples will get well of themselves, and these are, freedom from friction and free circulation of air around them. These requirements may be met by making a large excavation in a piece of cork, with a hole in the top to give free entrance to air. This is to be set over the nipple, and worn constantly when the child is not nursing.

Ligation of the Cord.—It has been suggested that the cord should be ligated with a piece of elastic tape. The advantage claimed is that the elastic tape will follow the cord as it undergoes the natural process of shrinking, and thus prevent the occurrence of hemorrhage.

Rigor subsequent to Delivery.—One writer has not found any theory that satisfactorily explains this phenomenon, therefore presents one of his own, which is substantially that these rigors occur because of the removal of a body from the cavity of the uterus that (together with the uterus itself) has a higher temperature than the body of the mother; hence an abstraction of heat from other parts of the body, to make up for a local deficiency suddenly developed.

Dr. GARRISH hails the occurrence of these rigors, for he had never seen a case of post-partum hemorrhage under such circumstances.

Extra-uterine pregnancy, pelvimetry, chloroform in labor, resuscitation from impending death from chloroform by everting the patient and at the same time practising artificial respiration, improvements in obstetrical operations, and other topics, received passing notice according to their relative importance. Altogether the report was a valuable contribution.

Remarks were made by Drs. Garrish, Foster, Burall, Sell, and Messinger.

MESSRS. MACMILLAN will publish shortly "A Course of Practical Instruction in Elementary Biology," by Professor Huxley, assisted by H. N. Martin.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 1, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

AFTER the preliminary business, DR. GURDON BUCK exhibited a new instrument for treating

ANEURISM BY COMPRESSION.

He did not claim any originality in its construction, but it was a modification of a very elaborate French instrument he had employed in the treatment of a case of femoral aneurism without success, and he believed that it would meet all the indications, without having any of the objectionable features which that instrument possessed. He expressed a willingness to loan it to any gentleman who might have a case of this kind to treat, for he was desirous of seeing how it would operate.

THE PATHOLOGY AND ETIOLOGY OF PULMONARY PHTHISIS IN RELATION TO ITS PREVENTION AND EARLY TREATMENT.

DR. E. DARWIN HUDSON read a paper upon this subject in which he first clearly presented all the theories concerning the nature of the disease that have been brought out since the time of Laennec, and concluded what he had to say upon *Pathology* by referring to the part which the adenoid tissue of the lungs plays in this grave affection. The existence of lymphoid tissue is established in the histology of the lungs, and the theory that this tissue is the soil for a new departure explains to us two facts, namely, why it is: 1. That miliary tuberculosis, without caseous masses, is so frequent in infants and young children; 2. That miliary tubercle, whether in children or adults, so often leads to death without softening or destruction of lung tissue. In the light of this theory, an exclusive or specific dyscrasia is derived, and depressing conditions, bad hygiene, severe surgical cases, etc., may become the causes of pulmonary phthisis.

ETIOLOGY.

We recognize predisposing and exciting causes. Modern etiology asserts that scrofula and tuberculosis are one and the same, and denies that there is a peculiar tuberculous diathesis; that hereditary taint is the only cause; and that every child born of consumptive parents is from birth to death threatened with the same disease.

All statistics have failed to prove hereditary taint as the only or chief cause, but on the other hand, phthisis is liable to be developed whenever nutrition becomes seriously impaired or the blood invaded by septic matter.

Among the predisposing causes were mentioned malnutrition, bad air, improper food and lack of assimilation, violation of sanitary laws, etc. In this category we therefore have, rebreathed air, depressing influences of city life, such as relative inactivity, sedentary habits, etc. Chest expansion may be regarded as one of the most important agencies in warding off influences which, if permitted to go unrestrained, will lead to tubercular phthisis. Certain trades cramp the chest, volatile emanations poison the atmosphere; these, with many other influences, lead to the production of catarrh and interstitial irritation in the air-passages.

Inflammatory thoracic diseases were regarded as prominent exciting causes, because they may awaken a dormant predisposition into an actual disease. As regards *pneumonia*, it is the general experience that uncomplicated cases resolve completely and leave no

trace of disease. It is equally true that when influenza and broncho-pneumonia are present, and also when pulmonary inflammations assume a typhoid type, that there is a greater mortality, and a greater number of cases terminate in pulmonary phthisis than when these conditions are absent.

Bronchitis was regarded as an exciting cause, although this is denied by many.

Thoracic inflammation of any form, however, is harmless when the constitution is sufficiently strong to permit the individual to come out from under its influence. It is the power the system has to resist these affections, bronchitis, etc., which determines the insignificance or gravity of the attack. Irritation of the throat, by provoking continued cough, may give rise to bronchial catarrh, and in this way lead to the development of phthisis.

Plastic exudation upon the pleura may be an exciting cause. The thickening and adhesions that result from a pleurisy may develop a hyperæmic condition in the underlying pulmonary tissue, which will result in inflammation, and the inflammatory product may undergo degeneration and become crude tubercle.

It has always been held that the old adhesions found between the pleura pulmonalis and the pleura costalis are very commonly the result of inflammation secondary to changes in the lung; and may it not be assumed with safety that the frequency of plastic adhesion justifies the conclusion that they may also be a cause of pulmonary phthisis? There is no reason why the inflamed pleura may not cause injury to the lung, the same as inflammation of the meninges of the brain or the pericardium do harm to the organs which they cover.

A cold and changeable *climate* favors the development of phthisis.

As regards *hemoptysis*, a bronchial hemorrhage is perfectly compatible with health. Local engorgements may occur, and bronchial hemorrhage be of benefit, provided the blood is not retained in the bronchi, for the lodgement of blood in the bronchi is frequently followed by disastrous consequences. From what has been said upon the pathology and etiology of the disease, we are led to the following conclusions, which have a bearing upon the questions of prevention and early treatment:

1. Dyscrasia, or predisposition, is largely accumulative, and is the result of the predisposing influences mentioned, which sanitary regulations may to a great extent remove.

2. Inflammatory attacks are the chief exciting causes of pulmonary phthisis, whether in systems previously healthy or otherwise, and may be largely averted by selection of a proper climate to live in, and avoiding exposures; or, at least, they may be rendered comparatively trivial in their effects.

These conclusions lead us, while studying the subject of treatment, to the consideration of diet, clothing, exercise, ventilation, purity of water-supply, management of children, so that they shall be the least liable to catarrhal sequelæ; proper method for maintaining a perfect circulation, normal temperature, cleanliness of the skin, etc., etc.

Injudicious and too frequent bathing is injurious, and therefore should be avoided.

Early arrest of the disease should be attempted, whether it manifests itself simply as a local lesion, or is complicated by dyscrasia. The outline of treatment, with this end in view, is embraced under three heads: 1. Food, which should be nourishing and easily assimilated; 2. Chest expansion, which is the best means of fortifying against the occurrence of in-

flammatory diseases, and, at the same time, secures functional activity of the lungs; 3. Climate.

Cod-liver oil was regarded as an agent of nutrition, and many times can be made more useful by the addition of phosphates, iodine, etc., which increase the general nutrition of the blood. Ammonia and quinine were mentioned as drugs to be employed: ammonia, because it is a diffusible stimulant, and favors the removal of mucus; quinine, because it has the power to diminish the temperature, and prevent degenerative changes in the tissues.

DR. LEAMING remarked that, so far as the general character of the paper was concerned and the views presented, he agreed with the author; but, that phthisis is essentially an inflammatory disease in all or in the greater majority of cases, according to the views of German pathologists, he did not agree. No doubt many of the cases are inflammatory at their commencement, and the inflammatory products are followed by tuberculosis, which causes death; but he believed that this was not so much the case from bronchial inflammation as from plastic exudation into the pleural cavity.

The exudation of plastic material upon the surface of the pleura at once interferes with the circulation and nutrition of the lung, and, when large in amount, may reduce the circulation through the lung perhaps to one-third the normal quantity. Such a reduction must have an immediate effect upon the lung at the very beginning, and does do so to such an extent that, directly after such an exudation has been poured out, hæmoptysis not infrequently occurs—sometimes very extensive—and is a bronchorrhagia. There are many such cases in which the entire trouble is resolved by this call of nature, and the exudation is taken away by this conservative act. If the plastic matter, however, becomes older, and partly organized, it is a permanent trouble, and the circulation is so far permanently impeded. This continued, hyperæmia occurs, lowering of the vital condition of the part is developed, and, as he would claim, it is very apt to be followed by tuberculosis. At all events, we have degenerative changes going on, and we have destruction of portions of the lung, but whether it is simply caseous degeneration or tubercular, he considered as yet remaining unsettled. He regarded it as impossible to prove that it was not tubercular; and, if the tubercle has been there and done its work, and we find nothing but inflammatory products left, what wonder?

Reference was then made to a case which fell under his observation in St. Luke's Hospital, where blood had been drawn into the lung below the tidal air, and finally produced abscesses. Before this termination took place, however, a large amount of plastic material was thrown out over the pleura, and post-mortem verified this in every particular. It was supposed, previous to death, that the patient had pulmonary œdema, for there was an abundance of fine subcrepitant râles and other symptoms indicating this condition, but after death no collection of fluid was found in the air-cells; they were entirely pervious, but, as indicated, a large amount of plastic matter was found covering the portions of lung over the places where the blood had lodged in the bronchi.

From his own clinical experience he believes that the subcrepitant and mucous râles in general are the result of inter-pleural exudation, and that they would be more correctly named by calling them plastic râles, fine and coarse, large and small. The effect of treatment is very often to remove them, and leave the patient perfectly well, but if left, the material may become organized and the source of subsequent trou-

ble. He referred to chest expansion as a hygienic and curative measure, and regarded it as especially beneficial. Gymnastics, with Indian clubs, etc., are not sufficient, but it requires full inspirations, repeated regularly and often, to properly expand the upper part of the lungs. Gymnasts may enlarge the muscles of the arms and chest, and in this manner even actually contract the chest capacity. The expansion of the lungs is something more than can be obtained by simple physical exercise. He further alluded to the fact that, in one of our public institutions with which he is connected, the rate of mortality among the children had been reduced from five or eight deaths a year to no deaths, or only an occasional one, by the influence of a simple but nutritious diet, consisting largely of milk.

DR. ELISHA HARRIS presented statistics showing the percentage of mortality in this city from phthisis, from the year 1820 to 1875. The maximum mortality is reached at the age of twenty-five. Between the ages of twenty and forty years 40 per cent. of all the deaths occur from this disease.

Probably this is not a high figure, because many persons are reported to have died of pneumonia, when they were actually suffering from phthisis, and died from a pneumonia engrafted upon it, which should be regarded only as a collateral cause of death.

He was of the opinion that there are healthy retreats in the United States where patients and those predisposed to phthisis may enjoy a comparative immunity from the ravages of the disease. He also believed that a proper spread and application of the true principles of hygiene would reduce the percentage of mortality very materially.

DR. GARRISH moved that the subject-matter of this paper be taken up for discussion at some future meeting.

DR. O'SULLIVAN seconded the motion with some remarks.

DR. WILLARD PARKER further seconded the motion, and believed that the subject should be kept under discussion until some conclusions are reached with which the Academy of Medicine will be satisfied as representatives of the profession of the city of New York.

DR. HUBBARD moved that the discussion of the paper take place at the meeting following the next stated meeting. Carried.

Adjournment.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from March 28th to April 3d, 1875.

GRAY, C. C., Surgeon.—When relieved by Assistant Surgeon Jackson, assigned to duty as Post Surgeon at Fort Brown, Texas. S. O. 52, Department of Texas, March 22, 1875.

WHITEHEAD, E., Assistant Surgeon.—Granted leave of absence for one month on Surgeon's certificate of disability. S. O. 52, c. s., Department of Texas.

ADAIR, G. W., Assistant Surgeon.—Assigned to temporary duty at Ringgold Barracks, Texas. S. O. 52, c. s., Department of Texas.

JACKSON, D., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Duncan, Texas. S. O. 52, c. s., Department of Texas.

Medical Items and News.

A DEPARTMENT OF PUBLIC INSTRUCTION IN THE MEDICAL SOCIETY OF THE COUNTY OF KINGS.—The following extract from the minutes of the Kings County Society will explain itself:

The Committee, to whom was referred that portion of the report of the Censors on the President's Address relating to the establishment of a Department of Public Instruction, having given the subject careful consideration, beg leave to report:

That the profession of medicine is the natural guardian of the public health, and is the only competent educator of the people in matters pertaining to the preservation of health. That the profession has, heretofore, held itself aloof from formal presentations to the public of the special instruction on which it could speak authoritatively, and that the only medical instruction that has been offered to the public has been through the medium of the Patent Medicine Almanacs, the advertisements of empirics, occasional voluntary contributions to the newspapers on special subjects, and the limited number of more or less valuable books on the care of the young and on general hygiene.

That the profession has everything to gain, in the way of dignity and influence, through the well-instructed intelligence of the constituency to which it ministers. The management of disease can alone be safely entrusted to the technically educated, and the discrimination between those who are and those who are not thus technically educated can be made by those, only, who have the requisite information on which to base accurate judgment.

That popular information on medical matters is demanded is sufficiently evident. Illustrations of this fact are furnished by the violent discussions on Vaccination in the daily journals a few years since, the liberal reports of Proceedings of Public Health Associations, the wide circulation of Brown-Séquard's Lowell Lectures, the report in last Sunday's *Times* of Dr. Peters' paper on Pneumonia before the Medical Library and Journal Association, and the five broad columns of the *N. Y. Tribune* of Monday containing Dr. Hartt's paper before the same Association on Medical Decadence.

That the rapid increase of medical investigation renders it impossible that any one man can be the accepted exponent of any one branch of medical science, and individual contributions to popular medical instruction are so likely to be tinged with the personality of the contributor as not only not to command the approval of the profession at large, but also not to command the unqualified acceptance of the public to whom they are addressed.

That the several State and Metropolitan Boards of Health are so surely working their way up to the approval and confidence of the profession and the public, as to confirm the opinion that the accumulated and generalized medical wisdom, of which their official character makes them the recognized exponents, is of value and of interest to the public.

That the representative character of the County Societies should carry authority to their utterances on matters which they might regard as useful or timely for general information.

That, in view of the foregoing facts, the Medical Society of the County of Kings may prudently take the initiatory steps towards making the County So-

cieties the authoritative and competent sources of popular medical enlightenment and instruction.

Your Committee, therefore, recommend the appointment of a committee to be called the Committee on Public Instruction, whose duties, jealous of the dignity of the profession and alive to the needs of the public, are defined and restricted as follows:

1. The Committee of Public Instruction shall consist of five members, whose term of office shall be for one year, commencing with the February meeting. They shall be appointed by the President.

2. Meetings of the Committee of Public Instruction shall be held at least once in each month, of which reports, with the names of absent members, shall be made at the next succeeding meeting of the Society. If any member shall be absent from two successive meetings he shall cease to be a member, but the President may reappoint him.

3. It is the purpose of the Committee of Public Instruction to communicate useful information on medical subjects to the public through the medium of the press. To this end it shall obtain, prepare or select suitable papers, which it shall send for publication to such newspapers or periodicals (not medical) as it may select. The writer's name or other means of identification shall not accompany any original (specially prepared) paper, nor shall the name of the author of any selected article be published when such author is a member of this or any neighboring Society.

4. In the report required in section two, the name of the author (when known) may, and the subject of each accepted paper shall be given, and, if the Committee of Public Instruction so recommend, any such paper may be read to the Society and discussed either before or after its publication.

Respectfully submitted.

BENJ. F. FESSENDEN.

CHAS. COREY.

ALEXANDER HUTCHINS.

DR. ERNEST SANSON, OF LONDON, AND THE COUNTY SOCIETY.—Dr. Sansom has recently been elected an honorary member of the Medical Society of the County of New York—not Honorary Fellow of the Medical Society of the State of New York, as our English exchanges have it.

The State of New York embraces a territory three hundred and thirty-five miles long by three hundred and eight miles in its greatest width, an area of 47,000 square miles, or very nearly as large as England. There are sixty counties in the State, all but four of these having societies called county societies. These send delegates to a State Society. New York County is the smallest of the whole, being limited to the area covered by the *City of New York*.

The other States of the Union have, most of them, State Societies, which send delegates to one society called the "American Medical Association." The "Medical Society of the County of New York" has a membership of about six hundred, and is the largest county society in the United States. It is this society which has honored itself by electing Dr. Sansom an honorary member.

THE QUESTIONS OF THE EXAMINATION at the Medical College of Ohio are published in the *Clinic* of February 27th.

FEMALE MEDICAL STUDENTS IN INDIA.—The Government of Madras, on January 11, issued its general orders on the admission of female students to the Madras Medical College, and on the course of study to be pursued.

MARYLAND UNIVERSITY SCHOOL OF MEDICINE.—At the commencement of this school, held on the first of March, fifty candidates received the degree of M.D.

A LUCID DESCRIPTION.—A hundred and fifty years ago, opium was highly prized, as it is at present, but its action was so little understood that a noted author said of it: "When it is given in too great a quantity it so thickens and glues the humors in the brains by its viscous parts, that the spirits which come forward to succor, not being able to dissolve this viscosity, are forced to stop and congeal likewise, by little and little, until at last they lose all their motion, whence it comes to pass that many do die upon the taking of opium."

DUPES OF QUACKERY.—Some simple folks in West Boylston, Mass., have just been "duped" in a very contemptible way. Two well-dressed scamps found out the deaf people in town, and then proposed to cure them for from \$50 to \$100 each, according to their extremity, asking, of course, an advance payment. Some paid from \$10 to \$20 down, and were ornamented with a wire contrivance which came over the top of the head and down behind the ears, and which they were to wear four hours a day for eight weeks, as it would keep up a current of electricity that would ultimately restore the functions of hearing entirely. The swindlers, of course, have gone, but some of the dupes are still wearing their foolish head-gear.

THE MEDICAL ASSOCIATION OF ALABAMA will hold its next annual session on the second Tuesday in April (the 13th), at Montgomery. This Association has just been constituted by the Legislature the State Board of Health.

THE MICHIGAN STATE MEDICAL SOCIETY will hold its ninth annual meeting at Detroit, commencing June 9th, 1875.

SUSPENSION OF A CANADA MEDICAL COLLEGE.—The Victoria Medical School of Toronto was closed suddenly in the middle of the winter session. The reason assigned is the want of a sufficient number of students to remunerate the Faculty.

HOMEOPATHY IN THE BROOKLYN HEALTH BOARD.—On the 26th of March, Dr. Van Clief, a homœopathic physician of Brooklyn, was appointed Sanitary Inspector against the remonstrances of Drs. Conkling and Hutchinson. Dr. Conkling said it was an insult to them, and Dr. Hutchinson said, if the Board was going to countenance such action, eclectics and clairvoyants should be appointed, in order that no injustice should be done; and he, therefore, moved that Mrs. Parkes, a clairvoyant, be appointed. Dr. Van Clief was, however, appointed as Sanitary Inspector, General Jourdan, Alderman Bergen, and Commissioner Palmer voting for him.

NEW MEMBERS OF THE COUNTY MEDICAL SOCIETY.—WILLIAM PORTER, Washington Heights, a graduate in Medicine at the University of Buffalo, N. Y., in 1851; SIMEON A. FOSTER, 333 W. 48th st., a graduate in Medicine at the Medical Department of the University of the City of New York, in 1867; JOHN JAUNCEY KETCHUM, a graduate in medicine at the College of Physicians and Surgeons, in 1867; WILLIAM NEWMAN, a graduate in Medicine of the University of the State of New York in 1874; FRANK RICHARD NEWMAN, 296 East Broadway, a graduate in Medicine at the Bellevue Hospital Medical College in 1874; JOHN PARSONS, a graduate in Medicine at the University of Iowa, at Keokuk, in 1864, at the Chicago Medical College in 1868, and at the Bellevue Hospital Medical College in 1875; CHARLES ELI BRUCE,

222 East 32d st., a graduate in Medicine at the Bellevue Hospital Medical College in 1873; WELCOME WHIPPLE SPRAGUE, Third ave. and 82d st., a graduate in Medicine at the Bellevue Hospital Medical College in 1875; DAVID F. FETTER, 262 W. 34th st., a graduate in Medicine at the College of Physicians and Surgeons.

THE AMERICAN DENTAL SOCIETY OF EUROPE will meet at Homburg, near Frankfort-on-the-Main, on the first Monday in August next.

INTERNAL USE OF SEA-WATER.—Dr. E. Lisle recommends sea-water as a valuable remedy in strumous, dyspeptic and anæmic cases. He has used it in the form of bread made with fresh sea-water, and also in combination with syrup, and with syrup, rum, and some flavoring essence.

THE PHILADELPHIA SCHOOLS have had large classes during the past winter, the Jefferson Medical College having conferred the degree of Doctor in Medicine upon one hundred and seventy, and the University upon one hundred candidates.

THE BERLIN ACADEMY OF SCIENCES has established a fund for the purpose of maintaining in that city a certain number who will devote themselves solely to scientific investigation, and will be relieved of duty as lecturers, teachers, etc.

APPOINTMENTS ON THE RESIDENT STAFF OF THE HOSPITALS.—*Bellevue*: Junior Assistants, Drs. John C. Kendall, John C. Cochrane, Raphael F. Hine, H. M. Silver, D. L. Wallace, P. Smith. Provisional Assistants, C. H. Thomas, R. Van Santvoord. Dr. P. Smith passed at a previous examination, but there being no vacancy at that time his appointment as junior assistant was deferred until the present. *Charity*: John H. Swazey, Fred'k M. Trask, Thos. W. Fullertlove, John T. Larew. Provisional, Nath'l Pinto.

THE MEDICAL UNIVERSITY OF PENNSYLVANIA.—The Library of this school has been increased by the addition of the Library of Professor Stillé, numbering 3,000 volumes, and has also received from Isaiah V. Williamson, Esq., property valued at \$100,000.

The Alumni Ward Fund now amounts to \$10,000.

THE NEW YORK DISPENSARY FOR DISEASES OF THE SKIN has been reopened at No. 203 East 27th street. *Surgeon in Charge*, Henry G. Piffard; *Assistant Surgeons*, William B. McGuire and Charles Schmidt.

A CARD.—The late DR. WESTERVELT, who was, in 1832, the Health Officer of the Port of New York, a short time before his death, wrote an elaborate paper upon the introduction of Cholera into New York City, in 1832. It is thought that this paper was placed in the hands of some medical friend for publication.

As said paper now becomes of great value as corroborative evidence to facts which have already been collected, as to the Cholera Epidemic of 1832, it is earnestly asked that the holder of said paper will communicate with the writer, whose address may be obtained from the publishers of THE MEDICAL RECORD.

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, April 12.—N. Y. Ophthalmological Soc.

Tuesday, April 13.—Amer. Microscop. Soc.; Yorkville Medical Assoc.

Wednesday, April 14.—N. Y. Pathological Soc. "The Relation of the Urine to Diseases of the Skin," by L. D. Bulkley, M.D.

Thursday, April 15.—N. Y. Academy of Medicine; Medical Assoc. Eastern Dist. of Brooklyn.

Friday, April 16.—Medical Library and Journal Assoc., "On the Elements of Diagnosis in the Different Stages of Disease of the Hip-joint," by Dr. C. F. Taylor

Original Communications.

TRACHEOTOMY WITH THE GALVANO-CAUTERY.

By GEO. R. FOWLER, M.D.,

BROOKLYN, N. Y.

ON March 17th, 1875, I was called to meet in consultation Dr. Domfield, in a case of membranous croup, occurring in Willie G., aged seventeen months. The child had been attacked three days before, and now presented the peculiar appearance of croup in its last stage; the *alæ nasi* being widely dilated, the epigastrium sinking deeply at each inspiration, and almost complete cyanosis existing. Pulse 140 and soft. Several convulsions had occurred.

The attending physician had given emetics, etc. I recommended inhalations of lime-water vapor, potass. bromid., and tracheotomy. The father hesitated in giving his consent to the latter, and we agreed to meet in an hour and invite Dr. Figueira to see the case.

At seven o'clock, no change for the better being perceptible, Dr. Figueira, Dr. Domfield and myself concurred in the advisability of opening the trachea. This I proceeded to do by means of the galvano-cautery.

A Byrne's caustic battery was used, of the very portable pattern manufactured by Shepard & Dudley, of New York. The knife was the short scalpel-shaped one, used by Dr. Byrne in some of the operations upon the uterus, held in a hard rubber insulated handle, and connected to the battery by the usual method.

The child having been placed upon a dining-table, the shoulders supported by a pillow, Dr. Figueira proceeded to administer chloroform. The battery was placed upon the table, at the child's left side, the connections made, and the plates lifted out of the solution.

All being in readiness the plates were lowered in the solution, and upon the knife becoming incandescent the first incision was made in the usual location, viz., from the cricoid cartilage to within a few lines of the sternal notch. The cautery knife was held precisely as one would hold an ordinary pen. The tissues were divided with extraordinary facility, the slightest contact being sufficient. The edges of the wound gaped widely, not the slightest trace of blood being visible to obstruct the view until the isthmus of the thyroid was reached, when an undue amount of haste was exercised on account of the patient having stopped breathing. At this point about one drachm of blood was lost, and even this would not occur in a similar case, as artificial respiration would have soon restored the patient for the few seconds needed to complete the operation.

Upon reaching the rings of the trachea the latter was easily recognizable. The caustic knife was now laid aside, a tenaculum inserted to steady the trachea, and the latter opened with an ordinary bistoury. Here a very small portion of blood was again lost, during section of the mucous membrane lining the trachea, and the areolar tissue adherent to the surface of the divided rings. The tube was readily inserted, and our little patient was soon comfortably breathing.

He rallied from the operation remarkably well, and drank brandy and water freely. The pulse remained as before for an hour, and then grew stronger and steadier. Not more than two drachms of blood was

lost, and, as before stated, a portion of this could have been avoided.

The patient slept comfortably for several hours, pulse and respiration constantly improving. The tube was occasionally removed and cleaned. At three o'clock, seven hours after the operation, a convulsion suddenly occurred. The tube was removed and found to be perfectly clear. At six A.M., three hours later, another convulsion occurred in which the patient expired.

The use of the galvano-cautery in tracheotomy was first introduced by M. Amussat in 1870. His patient, a lad of thirteen, was in imminent danger of suffocation from a foreign body lodged in the trachea. Dr. Amussat's method of operating consisted in passing a curved needle, armed with a double platinum wire, through the tissues overlying the trachea, and including a small portion of the anterior wall of the latter, in the loop which was formed by the needle emerging a short distance from the point of entry. The ends of the wire loop were then attached to the battery, and section made of the included tissues by gentle traction, no hemorrhage occurring. The foreign body was coughed out through the opening thus made, and in a week the wound was healed.

The advantages of cutting down to the trachea with the galvano-cautery knife are obvious. In the first place, the freedom from hemorrhage is a very important consideration. Secondly, as these operations are almost always done in the night-time, the incandescent platina knife lights up the bottom of the wound, and enables the operator to recognize almost every layer of tissue cut through. Thirdly, the wound opens widely and evenly, thus dispensing with retractors, and enabling the operator to obtain a distinct view. Fourthly, rapidity of operating, no time being lost in sponging and tying bleeding vessels.

I think it better, on reaching the trachea, to open it with a bistoury instead of with the cautery knife, for the reason that there is a greater immunity from danger of setting up a severe tracheitis; besides which there is very little blood lost in the section of the rings of the trachea by the common method. The inhalation of the steam from the hot knife, as it enters the trachea, would still further embarrass the respiratory efforts.

M. Bourdon, in 1873, described the operation as performed by M. Verneuil with the galvano-cautery knife. He speaks of the danger of cauterizing the trachea, and also of perforating its posterior wall. The avoidance of this danger by opening the trachea itself with a common scalpel or bistoury was proposed by MM. de Ranse and Maron in detailing a series of experiments performed upon dogs with the actual cautery in tracheotomy.

DR. FRANCIS CONDIE, M.D., who died on the 1st inst., in Delaware, at the age of 80, was a leading member of the medical profession in Pennsylvania. He was born in Philadelphia in 1796, and received his diploma at the University of Pennsylvania in 1818. He published in 1817 an abridged edition, with notes, of "Thomas's Practice of Medicine;" in 1824 a "Course of Examinations for the Use of Medical Students;" in 1831, a "Catechism of Health." His principal work was a "Practical Treatise on the Diseases of Children," published in Philadelphia in 1850, and of which four editions have been issued. Dr. Condie edited some of Dr. Fleetwood Chnrhill's principal works, and contributed to several medical periodicals.

A NEW SPLINT FOR FRACTURED JAW.

By FRANCIS H. ATKINS, M.D.,

ACTING ASSISTANT-SURGEON U. S. ARMY.

On the 6th of August, 1874, I was called to see a tramp (aged about twenty-six years), near Fort Wallace, Kansas, who, for a petty theft, had, the previous afternoon, received frontier justice at the hands of the aggrieved owner.

His head was badly bruised, cut, and swollen; the eyes closed; nose and mouth full of blood; his lower jaw fractured in two places, and the interior of the mouth so much lacerated and swollen that he could scarcely breathe or swallow. The jaw was broken (1st) at the angle on the right side, and (2d) between the left canine and left lateral incisor. The fragment—embracing the whole of the front and right side of body of jaw—was depressed, retracted, and drawn to the left side, in each direction about one-third of an inch, bringing the incisor behind the adjacent canine and below it; the right lower corner of face being strikingly depressed. At the angle there was no apparent displacement, though very free motion, crepitus, etc.

There being a complete absence of all the usual facilities for treating such cases, an attempt was made to wire the pieces together at the anterior fracture, but it failed, and on the 10th I applied a splint which I devised for the occasion, made of simple materials, that might be had at sea, etc., where such an emergency might arise.

The splint was made of a piece of hoop-iron, two inches long, and from one-third to one-half inch wide, with its corners filed smooth, and four small holes punched in it to correspond respectively with the spaces between the middle incisors, and between left-middle and lateral incisors, the line of fracture, and the space between the two left bicuspid.

The object in view was to attach a brace to the left side of jaw, so that the large fragment could be drawn forward, bound to it, and so be held in place. With a dental drill a small hole was made between the lateral incisors, and a space filed between the middle incisors. Between the bicuspid a natural opening existed near the gum.

The splint, being curved by stout forceps to suit the curve of the jaw, was first wired to the bicuspid through the corresponding hole in the splint; then one end of a fine, well-annealed, iron wire (suture wire) was passed into the hole in the splint corresponding to the space between the middle incisors, and its other end through the hole opposite the space between the left lateral incisor and canine, and through the corresponding interdental apertures into the mouth, where the ends were seized by small forceps, turned forward again and brought through the aperture between the left pair of incisors and out through the splint upon its anterior surface. By this means a loop was formed for the left central and one for the left lateral incisor. As soon as gentle traction was exerted on the wire ends, the fragment moved steadily upward and forward and towards the right, with an ease that was fairly surprising when contrasted with the great digital force previously required in attempting to replace the fragment.

When the wire was drawn firmly and clinched, the replacement of the fragment was absolutely perfect, and the outline of the face fully restored, and both remained so. A Barton's occipito-parietal bandage finished the dressing. Although the patient—against orders—constantly opened his mouth for greater ease

in swallowing, and even masticated to a certain extent, no further adjustment was required. Owing to the splint having been a trifle wider than necessary, a small abrasion of the lip occurred after several weeks, but was easily remedied, and might have been obviated had the splint been narrower. The splint caused no discomfort, and the man often remarked that his jaw "felt so easy."

Disinfectants were used freely in the mouth until the lacerations healed. He was well in about six weeks, having worn the splint continuously. In many cases sufficient interdental spaces already exist, but the injury to the teeth in this case was trifling compared with the serious condition of the jaw. A subsequent search through all the medical literature—standard and periodical—I had access to, has made me believe this splint sufficiently novel to describe in the RECORD—that noted in the Bellevue Hospital Report, MEDICAL RECORD, March 16, 1874, not excepted. Its simplicity would seem to recommend it in cases of much injury to the soft parts.

A CASE OF NOMA FOLLOWING INTERMITTENT FEVER: RECOVERY.

By JOHN H. RIPLEY, M.D.,

NEW YORK.

ON August 24, 1874, I was called to Morrisania to see Alma V., at 4 years, a previously healthy and robust German girl. The mother stated that about 4 P.M. on the 16th the child was taken with a severe chill, which lasted an hour, and was followed by a high fever, which continued till 8 A.M. next day. After the subsidence of the fever she appeared pretty well until 4½ P.M. (17th), when she was seized with another chill, which was succeeded as before by fever, lasting till 9 o'clock on the following morning. These symptoms had been repeated daily since until the last three days, during which the fever had been continuous. Her appetite had declined from the beginning of the sickness, and for several days her stomach had rejected the most simple diet. Her bowels were constipated, and urine scanty and high-colored. I found her restlessly tossing about the bed, and her extreme nervous irritability made a careful examination difficult. She was much emaciated, her countenance sallow, and skin hot and dry. The tongue was moist, but coated. Respiration 40 and pulse 130 per minute; temperature, 103½°; abdomen retracted, and its muscles flaccid; heart and lungs normal, except slight bronchitis; spleen, markedly enlarged. The physician in attendance had administered quinine in various forms, both by stomach and rectum, but it had not been retained. Small quantities of ice-cream and mutton soup were recommended as nourishment, and the following prescription ordered:

R. Quinæ sulphat. gr. xxiv.

Elix. tarax. comp. ℥ iij.

M. S. Two teaspoonfuls every two hours.

25th, 12 M.—Pulse 120; temp. 102°. Slept better than for several nights, and has retained medicine and nourishment. Is less restless and looks better. My attention being called to "sore mouth," I found a slight ulceration at the borders of the gums of left upper incisors, and added to previous treatment small doses of chlorate of potassa.

26th, 12 M.—Pulse 120; temp. 99°. Takes nourishment well, and has been playing with her toys this morning. Quinine mixture to be given every four hours. No other change in treatment.

28th.—Mother says child's face got very much swollen yesterday, and her breath smelled so badly she could not stay near her. I found the left side of upper lip and left cheek enormously swollen, and the submaxillary and lymphatic glands of same side enlarged, and cellular tissue of neck infiltrated. The lip was smooth, pale and shining, and painful to the touch. On raising it and examining its mucous surface, I discovered a portion situated just within its angle, the size of a two-shilling piece, involved in an ash-colored slough, from which flowed a thin and very fetid fluid. On removing the sphacelated mass, a deep ulcerating and comparatively bloodless cavity was exposed, which extended half an inch above the reflection of the mucous membrane upon the gums. The superior maxilla opposite was denuded to a considerable extent on both sides, and the two incisors had fallen out. Patient was quite drowsy; Pulse 88; temp. 99°. The whole diseased surface was thoroughly cauterized with pure carbolic acid, and ten grains of chlorate of potassa, and five drops of the tincture of muriate of iron, directed to be given every two hours; also egg-nog or milk-punch every three hours.

29th.—Considerable diminution of swelling of the parts, and less fetor. Two more teeth (canine and first molar) have fallen out. Pulse 88; temp. 99°. Applied solution of equal parts of carbolic acid and water and continued medicine and nourishment.

31st.—Patient sitting up, and swelling nearly gone; no extension of ulcer; appetite returning. Pulse 92; temp. 98.6°.

September 1st.—Looks feeble; has remained in bed to-day and refused food; ulcer granulating. Ordered brandy to be increased and potassa mixture to be continued at intervals of four hours.

3d.—Yesterday, sat up part of the day, and had a fair appetite, and to-day continues better.

6th.—Patient gaining in flesh, and ulcer rapidly healing.

15th.—Contrary to instructions, the medicines were discontinued on the 8th. On the 12th, the appetite declined, and the mouth began again to be painful, and its odor offensive. I found the cheek considerably swollen, and at site of old ulcer the disease was making fresh ravages. A resumption of the treatment soon checked the relapse, and effected a permanent cure. On the 23d of the following month I removed, with my dressing forceps, a necrosed triangular piece of the superior maxilla, whose base contained the cavities of the four lost teeth, and whose sides measured about an inch each. The resulting deformity of the face is marked. The lip is thinned by loss of tissue, and, unsupported, sinks back into the mouth, giving the child a senile expression.

I have given the history of the malarial fever in this case somewhat fully for two reasons. 1. It appears to me to have been the sole cause of the secondary and more grave disease; for, as I have before stated, the child had enjoyed excellent health previous to this illness, and, I may add, took no mercury during her sickness. 2. It illustrates the value of the Compound Elixir of Taraxacum as a vehicle of quinine. My attention was called to it several years ago by Prof. Jacobi, and, since that time, I have almost invariably prescribed it with quinine, when administering the latter to children. It completely covers the bitter taste of the salt, and is rarely vomited, even by infants a few months old. The original formula, published in the *Am. Journal of Pharmacy*, January, 1870, has been modified a good deal by different apothecaries, and some of them have improved it—notably, Bendiner & Becker, corner of 10th street and 3d avenue. The quinine should not

be dissolved nor the mixture kept too long before using. The proportion is about a fluid drachm of the elixir to a grain of quinine.

The course of the local disease shows, I think, that it was controlled by large doses of chlorate of potassa.

313 E. 53D STREET.

CASE OF

PERITYPHLITIC ABSCESS.

By J. H. POOLEY, M.D.

YONKERS, N. Y.

DECEMBER 5th, 1874, I was called to see Annie M—, a fine healthy-looking Irish girl fifteen years of age, who had never had any serious illness in her life.

For two weeks before I saw her she had been complaining of obscure uneasiness, increased at times to rather severe pain, referrible mainly to the right iliac fossa, and spreading somewhat over the surface of the abdomen. I found her in bed, lying on her back, with her legs drawn up, with an anxious expression of countenance, and very much afraid of being touched or moved; skin somewhat hot and dry (temperature not taken), tongue coated, pulse 100, appetite gone, bowels obstinately constipated.

She complained of pain in the right iliac fossa, and in the hip and knee, that in the hip being most severe. There was tenderness on deep pressure in the iliac region, none over the abdomen; complained of severe pain when the hip was moved. Ordered hot poultices to be applied over the iliac region, morphine to the extent of relieving pain, and five grains of sulphate of quinine three times a day.

Dec. 6th.—Much freer from pain, partially under the influence of morphine; takes abundance of fluid nourishment, milk and beef-tea; lies in the same position, with the thigh flexed at right angles to the pelvis, and rigidly fixed, resists any attempt to move it; abdominal tenderness about the same.

The patient continued in almost the same condition, without any daily alterations worthy of notice, until Dec. 10th, when there was an increase of tenderness in the right ilium, which also extended pretty generally over the abdominal surface, increase of fever, with great restlessness; refuses almost all nourishment; has had one hard passage from the bowels since last record. Increased the quantity of morphine, continue other treatment.

Dec. 11th.—Condition much the same as yesterday; tenderness increased; has vomited some greenish material. I think I notice to-day, for the first time, some fulness in the right iliac fossa. Continue treatment.

Dec. 12th.—The swelling is quite perceptible, fever higher, pulse 110, pain not so severe.

Dec. 15th.—Has had a slight chill; at the time of visit, 10 A. M., is sweating profusely, swelling increased, otherwise condition unchanged, pain more tolerable, takes nourishment better than for the last few days. Same treatment.

Dec. 20th.—Much worse, pulse 120, moaning with pain, abdomen very tympanitic, vomits frequently a greenish material, and is much distressed thereby.

Swelling quite prominent, cannot tell whether there is fluctuation, for the simple reason that it is so tender she would not even permit the fingers to approach it; proposed to cut down upon and open the abscess, which I felt quite sure existed, but the parents would not listen to it. Increased the dose of morphine, and substituted warm fomentations for the poultice, which seemed to distress her by its weight.

Dec. 24th.—Opened the abscess. The patient being placed fully under the influence of ether, an incision three inches in length was made about an inch and a half above Poupart's ligament, but not exactly parallel to it, being rather over the greatest prominence of the swelling. The incision was carried down through the various layers, but without being able to distinguish them accurately, they were so blended together by inflammatory action, until the fascia transversalis was reached; the moment this was opened there was a tremendous gush of matter (estimated at nearly half a pint) of a dirty-gray color, and so unbearably offensive that I was obliged to retreat for a moment into the fresh air. After the evacuation of the abscess the finger could be introduced into a considerable cavity, where the caecum could be distinctly felt, and also the iliac artery plainly pulsating under the finger. A tent of lint was introduced, a large poultice applied, and the patient put to bed, ordered to be kept very quiet, and morphine if pain was complained of, otherwise not. Visited the same evening; she was found very comfortable, had not needed any morphine; on changing the dressing, some shreds of necrotic connective tissue were drawn out of the wound.

Dec. 25th.—Patient in excellent condition, free from pain, but quite weak; while syringing out the abscess with a solution of carbolic acid ʒss. ad ℥i. there was discharged what appeared to be the whole appendix vermiformis in a sloughy, pulpy condition; no foreign body was found at this or any other time, though of course one may have been discharged in the first violent gush of matter when the abscess was opened. Ordered daily syringing out with solution of carbolic acid, and to take ten drops of tinct. ferri chloridi every three hours.

From this time everything went on excellently well; the patient improved day by day, and though the discharge continued free and had a feculent odor for the first week, it then began to diminish, and completely lost its odor. Picked oakum was substituted for the poultices, and she began to sit up, though the abscess did not entirely close till the beginning of February, 1875, at which time it was completely healed up, and the patient is now in perfect and robust health, without the slightest remaining inconvenience from her recent dangerous and alarming illness.

This is the first case of the kind which I have encountered, and therefore I have little or nothing to add by way of remark to the simple record given above.

No doubt it would have been better to have opened the abscess a few days earlier, but, as already stated, the parents would by no means consent until it was almost forced upon them. It seems to me that what may be called the anatomical method of opening by a free, regularly planned incision, is preferable to any form of puncture, and, if other cases occur to me, I shall confidently follow it until convinced of the contrary.

This case is referred to (as "communicated") by Dr. Gouley in his recent admirable paper read before the State Medical Society, and I place it on record to complete that reference, and as a contribution to the literature of an important and interesting subject.

DRY SYRUP is the name given to concentrated medicinal compounds in powders, which, when dissolved by the aid of heat in the proper menstruum, make the syrup of the article employed. The *Chemist and Druggist* says that the plan seems well adapted to almonds and similar articles, the liquid syrup of which is with difficulty kept from change.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

WAS IT TYPHOID FEVER?

THE interest in the following case turned upon the difficulty in diagnosis. A male patient, about forty-five years of age, was admitted four days ago, who said that he had been sick eight weeks, and that his trouble began by getting "all chilled" while driving a truck. His answers, however, were given in such an indifferent manner that but little reliance could be placed upon them. He also stated that about *ten days* ago he got "swelled all over," but the house physician said there was no general dropsy present when he came in. Since admission to the hospital his temperature had varied from 100° to 103°. At first there were morning exacerbations, but during the last two days slight evening exacerbations had been present. It should, however, be stated here that quinine had been administered, and the cold pack used several times. Although the temperature had pursued an erratic course since admission, doubtless the tendency in that direction had been increased to some extent by the treatment employed.

There was nothing specially characteristic about the countenance of the patient. The tongue was red at the tip, brown and dry upon the edges, and the brownness and dryness extended well back towards the roots, but there was no sordes upon the teeth or lips. His respiration was easy and full, and was both abdominal and thoracic. Upon percussion, some dulness was found over the lower portion of both lungs posteriorly. Upon auscultation, feeble respiration was discovered over the left lung behind; but over the right, respiratory murmur was absent, except upon full inspiration or with cough, when fine crackling sounds could be heard. There was no bronchial breathing present, but dry râles were heard over both lungs. Vocal fremitus was more marked upon the right than upon the left side, especially over the region where the crackling sounds were heard.

The first sound of the heart was absent at the apex, and was very indistinct over the entire precordial region.

Firm pressure gave rise to slight gurgling in the right iliac fossa, but did not produce any pain. A slight amount of tympanitis was detected by percussion, and the blow gave rise to some pain, particularly over the right iliac region. There had been *only one* loose discharge from the bowels since admission, and that was of a yellowish color.

The capillary circulation was feeble, indicating failure of heart power rather than obstruction to the return circulation. His pulse was 108, irritable, and easily compressed. The pupils were normal, and the urine contained only an abundance of lithates.

The spleen and liver were of normal size. Over the abdomen, thorax, upon the arms, and to some extent upon the legs, was seen an eruption that consisted of spots about two lines in diameter, of a circular shape, a trifle elevated, and did not disappear upon pressure. The spots were not of a bright rose color, but had more of a mulberry hue. During the last two days, some of them had presented more of the appearance of the characteristic rose-colored eruption of typhoid fever. The blood of the patient had not been examined, and there we have the complete history of the case. The

question was asked, "What is the matter with this man?" The visiting physician expressed the opinion that the diagnosis could be narrowed down so that it would rest between two diseases—namely, typhoid and remittent fevers. He was inclined to the opinion, however, that it was a case of typhoid fever, but at the same time regarded it as one of those knotty affairs that required careful study before a correct diagnosis could be made.

If the statement of the patient that he was taken sick eight weeks ago was true, and his present condition was but a continuation of that attack, it could hardly be said with safety that the eruption seen was that of typhoid fever. If, ten days ago, the patient was attacked with typhoid fever, the diagnosis could hardly be established by the appearance of the eruption, for the ordinary characteristics were absent, and it had not been observed a sufficient length of time to determine how long it would continue in one place or how long it would remain upon the patient.

The remissions of remittent fever may cease after the first four or five days, and then the disease continues as a continued fever. When this occurs, the distinction between it and typhoid fever cannot be drawn except by an examination of the blood. (Pigment is present in the blood of a patient sick with remittent fever.)

As a rule, there is no eruption present in remittent fever. Occasionally, however, an eruption is present, but it has no characteristic appearances, and is probably due to some nervous or blood changes. The fact that a patient has had one liquid discharge from the bowels, when taken in connection with other symptoms, may be of great value in making a diagnosis. Dry râles are to be expected in a case of typhoid fever, and the pulmonary œdema, such as was present in this case, is not of infrequent occurrence. The pulmonary œdema accounts for the dulness upon percussion. Cases of typhoid fever in which the temperature pursues an irregular course are not very infrequent. At this season of the year and in this locality, where malaria is present in abundance, the regular course of typhoid fever is very liable to be changed. The condition of the pulse, tongue, etc., clearly indicated the use of stimulants and nourishment, whatever the disease shall prove to be.

PARENCHYMATOUS HEMORRHAGE.

This case was one that suggested some thoughts concerning the varieties of hemorrhage the surgeon may meet with, and the measures to be resorted to for controlling them. The special form, however, to which attention is directed in this note is called *parenchymatous*, and is that which comes from minute arteries and radicles of veins. It is best described by the term "welling up." For instance, in this case it came from a deep-seated wound in the neck after an operation, and it was remarked that the same thing might occur in connection with deep-seated wounds in the perinæum and elsewhere. After all the arteries have been secured, all the veins compressed, and practically all oozing from the surface has ceased, still this form of hemorrhage may occur and prove troublesome to the surgeon. The wound fills up rapidly; the blood "wells up" and overflows. It was remarked by the surgeon that this kind of hemorrhage is usually quite easily arrested by packing the wound with lint, either with or without any styptic (the supposition is that every vessel has been ligated that is necessary), and then bringing the edges together and securing them with a continuous suture. In this manner the entire wound is packed and subjected to the pressure of the

lint. At the end of twenty-four or forty-eight hours remove the sutures, allow the edges of the wound to gape, but do not remove the lint until suppuration has been established sufficient to float it out, or allow of its easy removal. By the time this amount of suppuration has been established, sufficient adhesive inflammation, as a rule, has been set up to permanently close the minute ramifications of blood-vessels that permitted the hemorrhage.

CONTRACTION OF CICATRIX IN CASES OF EXTENSIVE BURNS.

A female patient was noticed who had an extensive ulcerating surface upon the legs, in consequence of a severe burn. To facilitate cicatrization, skin grafts had been set all over it. The question arose, Is the cicatrix formed in this manner as liable to contract and produce deformity as that which is formed when the ulcer is permitted to heal from circumference to centre unaided?

One of the consulting surgeons held that the cicatrix formed by grafting is less liable to give rise to troublesome deformities, because it is softer and more yielding, and therefore grafting should be resorted to in every such case, on account of the ultimate benefit that is to attend the process.

One of the visiting surgeons remarked that we had not yet had sufficient experience to enable us to decide with safety that the tissue formed by skin-grafting is any less liable to contract than when permitted to heal in the old-fashioned manner.

A METHOD FOR REMOVING LIGATURES THAT HAVE BEEN APPLIED TO VESSELS OF CONSIDERABLE SIZE.

It occasionally happens that the ligature thrown around a large artery, as, for instance, in the case in question, the femoral, after an amputation, delays coming away for a long time, because the destructive changes which are to occur in the coats of the vessel have been retarded in such a manner as to prevent its removal. This more commonly occurs after ligating large vessels, because there is greater liability of not completely severing the internal and middle coats when the ligature is applied, but it may happen after smaller arteries have been tied.

First, then, it is well to leave the extremities of the ligature full length, and tie them together at the end, so that it will be known to what vessel they belong. If their removal is delayed, it may be facilitated in the following manner:

Place a stick or pencil between the ends of the ligature, and then twist them into a cord by turning the stick around and around. Make sufficient tension upon the ligature to prevent kinking and continue to twist it until the knot in connection with the vessel is reached; then, slowly turning the stick, you will be able to make the twist in the ligature extend *beyond* the knot, and thus make additional constriction upon the vessel. Now, keeping the cord tense, lay the piece of stick upon the limb, and secure it with a piece of adhesive plaster. Perhaps the following day you will be able to make one or two more turns, being careful to keep the cord tense, so that it will twist the entire length, after which you will secure the stick as before. By pursuing this plan from time to time you may have the satisfaction of seeing the ligature come away entirely, perhaps within two weeks.

CIRRHOSIS OF THE LIVER.

The particular symptom noted in this case was diarrhœa alternating with constipation. It was re-

garded as an indication of chronic intestinal catarrh. It was remarked by the visiting physician that the existence of this condition in a person addicted to the use of alcoholic drinks, taken upon an empty stomach and undiluted, was a pretty certain sign of the beginning of cirrhosis of the liver; and that, in some cases, such a diarrhoea was the only symptom of the disease present.

CHRONIC VOMITING, ACUTE GASTRITIS, AND PLEURISY.

A few points were brought out by the visiting physician, while commenting upon the following case, that may be of some interest. The patient was a man about 40 years of age, a politician, who had been in the habit of using alcoholic drinks quite regularly for some time, and, as a result, had suffered more or less from vomiting. About two weeks previous to his admission to the hospital, he was exposed to cold, and, soon after, attacked with severe pain in the region of the liver, which was accompanied with tenderness, some fever, and was followed by a very great aggravation of the vomiting. His stomach became very irritable and rejected everything that was taken. The incessant vomiting had continued only a short time, when a hacking cough appeared. A moderate amount of tympanites was present. The patient was not jaundiced. How were these symptoms to be explained? First, the incessant vomiting was due to an excessive congestion of the mucous membrane of the stomach of an inflammatory character, and the exposure to cold had excited disturbances in a liver already under the influence of alcohol, which had given rise to the excessive congestion. In other words, it had changed a condition of chronic congestion into an acute inflammatory one. The gastritis was followed by duodenitis, and from this the inflammation extended into the bile-ducts, spread to the tissue of the liver, and gave rise to hepatitis. From the hepatitis, perihepatitis was developed, and that in turn gave rise to diaphragmatic pleurisy, which accounted for the short, hacking cough, etc. The perihepatitis had also given rise to peritonitis, which explained the presence of the moderate amount of tympanites. Thus the case was unfolded, and the above were believed to be the successive steps in its progress. Leeches had been applied over the region of the liver and stomach for the purpose of making a localized depletion, and in that manner to act upon the general inflammatory condition, through the nervous system.

Nothing that had been done for the patient had proved of very much service, and withal he was very sick.

In connection with this case the following prescriptions were mentioned:

For acute gastritis, such as occurs in cholera infantum:

R. Calomel. gr. $\frac{1}{4}$.
Acetate of lead. gr. $\frac{1}{3}$.
Opium. gr. $\frac{1}{6}$.

M.

This may be administered every half hour. For the acute gastritis met with in cholera morbus, the following has been used with almost invariable success after administering from three to five doses:

R. Acetate of lead. grs. viij.
Acetate of morphia. gr. i.
Camphor water. \mathfrak{z} i.

M.

In this prescription the lead is precipitated, but that makes no difference except that it necessitates shaking

the bottle before using. A teaspoonful is administered every fifteen minutes, or immediately after each vomiting spell, if it is rejected by the stomach.

Progress of Medical Science.

ANOTHER CASE OF AN EXTRAORDINARILY HIGH TEMPERATURE WITH RECOVERY.—In THE RECORD for March 27th a case was referred to in which the temperature rose to 110° F., and recovery ensued. The following case, however, related by Mr. J. W. Teale, at a late meeting of the Clinical Society of London, is far more remarkable. It is as follows:

A young lady was thrown from her horse, in the early part of September, 1874, and sustained a fracture of two ribs and some obscure injury to the spine. In due time the fracture united, but pain and tenderness over the sixth dorsal vertebra persisted.

Symptoms of spinal meningitis set in, and the temperature, which had regained the normal shortly after the accident, began to rise. One month after the accident it was 101° F., and in another month it had reached 105°. Between the 8th and 12th of November, it fluctuated between 110° and 118°, reaching subsequently 122°, on two occasions, and falling in the interval to 114°. For the next three weeks the temperature varied between 108° and 122°. Throughout December, it fell as low as 110°, during the first half of the month, rising to between 112° and 114° during the second half; in the beginning of January, it rapidly fell to 104°, becoming normal on the 10th of the month. The general condition of the patient did not seem to have been one of extreme danger, except during the highest range of temperature. The pulse never rose above 120°, and the respiration was not notably embarrassed.

The details of the case, with the thermometrical charts, have been published in full.—*The Lancet*, March 6, 1875.

EXTRAORDINARILY LOW TEMPERATURE AFTER EXPOSURE TO COLD.—There have been a number of cases reported in which the temperature of the body has fallen very far below the normal standard and yet recovery has taken place. Bouchut has collected a large number of these cases. In this connection the following is interesting:

Professor Nicolaysen was called upon to treat a man forty-one years of age, who one winter morning was carried insensible by the police into the hospital. The man had been found in the street, where he had passed the night (the thermometer having stood at 21° Fahr.). The whole body was found to be cold, and the extremities were rigid. The skin was pale, and the respiration and pulse were weak and irregular: the pulse could not be counted. The clothing was removed from the patient and he was wrapped in blankets. After diligent rubbing he revived a little, and his limbs moved slightly. Some cold water, at a temperature of about 45° Fahr., was then injected per anum. Subsequently artificial respiration was tried in addition to the continued rubbing, and the temperature of the room was gradually increased. After half an hour a thermometer warmed to 104° Fahr. was introduced into the rectum, for the mouth could not be opened sufficiently for the introduction of the instrument. After eight minutes the instrument recorded a temperature of 76.4° Fahr. The temperature then began to

rise, and the following were the observations made during the day:

9.00 A.M.,	Temp. of body,	79° Fahr.		
10.00 A.M.,	"	83° "	Resp., 20.	Pulse, 48-60.
12.55 P.M.,	"	90° "	" 18.	" 76
6.40 P.M.	"	101° "		

During the next day the pulse and temperature returned to the normal.

It was thought that the temperature of the patient had been lower than as stated above, for resuscitative efforts had been in operation for three-quarters of an hour when the first measurements were taken. The effect of the cold injection was thought to be very slight, but to determine what effect it might have had the following experiments were made: The same quantity of water at the same temperature was injected into the rectum of three individuals, among them the patient. The result was that after eight minutes the temperature was found to have fallen about $2\frac{1}{4}$ degrees. Nicolaysen concludes from this case that when no disease is present the temperature of the blood may be reduced to at least 81° Fahr., and yet the normal functions of the body may be again restored.—*Norsk Mæg. f. Læg.*, Jan., 1875.

THE DIAGNOSIS BETWEEN CALCULOUS AND TUBERCULOUS PYELITIS.—Dr. Basham, in writing on the above subject, gives the following three practical points to be considered in making a differential diagnosis in these two diseases: 1. The hæmaturia; its amount and frequency. 2. The purulent urine, in its time of appearance and constant or intermitting occurrence. 3. The presence or absence of progressive emaciation, with hectic fever, exhaustion, and death.

He says the hæmaturia in calculous pyelitis is occasional; in tuberculous diseases it is copious, and while the first stage lasts is continuous, there being no interval in which the urine is apparently free from blood.

In calculous pyelitis the purulent stage is slowly developed; the urine passing through a mucous stage of longer or shorter duration, succeeded by pus, which may appear intermittingly and may even for days be absent altogether.

In tuberculous disease, purulent urine succeeds the hæmaturia abruptly and almost immediately; there is no perceptible interval between the hæmaturia and the appearance of the pus. Moreover, the amount of pus in any given quantity of urine is far greater than is seen in the calculous form of the disease, and there is an amount of emaciation, accompanied by evening exacerbations of fever, never witnessed in the less fatal calculous form. This stage of the disease is sometimes accompanied by the development of a renal tumor, followed always by rigors and night-sweats, on account of the ureter becoming blocked by the increasing tubercular deposit in the submucous tissue of the tube. If a careful analysis be made of the antecedent symptoms, and due weight given to the order of their succession, a correct diagnosis may be thus formed.—*Practitioner*, March, 1875.

WOUNDS DRESSED WITH SILICATED COTTON.—M. Ollier has addressed a note to the French Academie des Sciences, and states that he finds great advantage in the use of the cotton dressing. One advantage is, that the dressings are made less frequently, which is important, because after each such occasion the temperature of the patient rises, and besides, the wound is exposed to the air, and consequently to the infectious germs that are in the atmosphere. But there is another advantage, which is, that, considering the matter of the absorption of infectious germs, it is important

not to break the granulous membrane that covers the wound, while frequent dressings are apt to do this. To obviate such a danger more fully, he advises that the cotton be covered with a silicated bandage, so that while the dressing occludes the germs completely, as it appears to, it also is immovable. He urges that this improved method may prove to be very useful in army practice, in the transportation of the wounded.—*Jour. de Méd. et de Chir.*, March, 1875.

SPECULAR EXAMINATION THROUGH A TRACHEAL WOUND.—Voltolini reports a case in which a piece of a nutshell remained impacted in the trachea for ten months; its presence and exact location being finally diagnosed by means of a new form of tracheal speculum devised by him, and its removal effecting a perfect cure. A child, aged ten, while playing with a bit of nutshell, placed it in the mouth, out of which it slipped into the larynx, and tracheotomy was rendered immediately necessary, by the dangerous suffocative symptoms which followed. An attempt to remove the tube was made some fourteen days later, but spasm of the larynx immediately recurring it was necessarily left in position. Notwithstanding the fact that repeated laryngoscopic and tracheal examinations were made from time to time, and various methods of treatment pursued during the following eight months, no foreign body was detected, although its presence within the air-tract was considered as probable by those in charge of the case. A second attempt at permanent removal of the tube, at the end of the above time, resulted, as before, in causing laryngeal spasm, followed, after reintroduction of the tube, by aphonia and some dyspnoea. In endeavoring to ascertain the cause of these new symptoms, the doctor undertook the careful examination through the tracheal wound, of the trachea, by means of a speculum, constructed on the principle of the *air speculum of Brunton*, and with it discovered the missing and long-sought for foreign body, firmly fastened to the posterior tracheal wall, by the impaction of its sharp extremities, and enveloped by the swollen mucous membrane. Upon enlarging the original wound, it was easily extracted, and a rapid and complete cure followed its removal.

Its location in the trachea, behind and below the canula, it being hidden by the latter when in position, will explain the fact of its being overlooked during the many laryngoscopic examinations that were made.

The case of Schroetter, of Vienna, where there was impaction of a partial set of false teeth with their plate in the trachea, and the one reported by Lefferts, of this city, of a ring lodged in the larynx for four years, are alluded to in the article, by the writer, as being coincident and of interest in connection with his own. For the latter he claims that it is the first in which a foreign body has been seen and authenticated after a long period of impaction in the trachea, and the first in which a foreign body has been diagnosed by means of a specular examination through a tracheal wound.

COPPER IN THE HUMAN ORGANISM.—In France, in cases of criminal poisoning, the medical expert is, as a rule, accompanied by a chemist to assist him; and in giving evidence before a court of justice, each is required to give an account of his work in his own especial department. Thus, while it is the duty of the chemist to search for the poison, the medical man looks for lesions in the body of the victim; notes are then compared, and if they do not tally with the results of works on the subject, the criminal is generally let off, not with the charge of manslaughter, but with

"extenuating circumstances." It is in this way that MM. Bergeron and L'Illôte, the former a medical expert and the latter a chemist, were engaged in the affair of Moreau, who was lately executed for having poisoned his two wives at St. Denis. On that occasion it was discovered that copper was the substance employed, though, during the lifetime of the victims, poisoning by corrosive sublimate was diagnosed, as the symptoms bore more of the character of the latter than of poisoning by copper. The two experts, having recalled to mind the teachings of the celebrated Orfila, that mineral substances are generally found in the great organs of secretion, such as the liver and kidneys, at once examined these organs, and there detected copper; they, however, wished to ascertain whether the liver and kidneys, in their normal condition, contained this metal. In concert together, they then directed their investigations with the view of solving this question, and had an opportunity of carrying them out on fourteen corpses, which they were certain had no copper administered to them during the latter part of their lives. The result of their inquiry was lately submitted to the Academy of Sciences, and it may be summed up as follows:

In two of the bodies, aged respectively 17, copper was found, but the exact quantity could not be ascertained; in eleven bodies, whose ages ranged from 26 to 58, the maximum quantity found was one milligramme; in one individual, aged 78, the quantity was a little over one milligramme. MM. Bergeron and L'Illôte explain the presence of copper in the liver and kidneys by absorption from constant contact with this metal in various ways, such as the use of copper utensils in cooking and other purposes, the handling of copper coin, etc. From these results, these gentlemen have come to the following conclusions, which are important in a medico-legal point of view:

1. Copper is constantly present in the organism, but can be detected in appreciable quantity only in the liver and kidneys. 2. The quantity detected in the greatest number of cases does not amount to two milligrammes, = $\frac{1}{15}$ ths of a grain.

A recent statement of M. Rabuteau is interesting in this connection.

Having examined the liver in a case reported by M. Bourneville, where the sulphate of copper had been given internally for epilepsy and where after death a considerable amount of copper was found in the liver, he found that a possible source of error in this case lay in the fact that copper is present in the alcohol which was used to preserve the specimens, and it is therefore necessary in such cases to preserve a specimen of the alcohol to decide whether or not it contains copper.

VARICOSE VEIN TREATED BY A NEW OPERATION.—Mr. Marshall, of London, mentions the case of a man who had suffered since he was sixteen years of age with a varicose condition of the left saphenous vein. For the relief of his trouble an operation was performed in November last, and it is described as follows: The patient was first directed to stand for half an hour with a carbolized cloth around the limb; chloroform was then administered, and the course of the tortuous vein was marked in ink. At each end of this mark the vein was ligatured in the following way: a pin was passed under the vein, a piece of bougie over it, and a figure-of-8 suture applied, bringing the two together so as to close the vein; two other similar ligatures were placed above the upper one at distances of two inches apart, and a fifth ligature was placed two inches below the lower one. The pins, bougie, and threads had all been previously carbolized.

Esmarch's elastic bandage was then applied to the whole limb, with the effect of completely emptying the varicose vein, even in the intervals between the several pins. A straight incision through the skin, from the top to the bottom of the ink-mark, was then made, and, with a knife and director, the vein was slit up along the whole of the exposed portion. As the vein then formed a very large, irregular, folded mass at the bottom of the wound, a ligature was passed around it above and below, and it was then removed with forceps and scissors, two large veins which opened into it being cut during the operation. A strip of carbolized gauze was then placed in the wound, and the limb put up in the complete antiseptic dressing. The operation was done under the carbolized spray. No bleeding whatever occurred. Unfortunately, erysipelas and suppuration, requiring an incision, occurred about one month after the operation; otherwise the patient did well. He was discharged in January last, with the diseased vein satisfactorily obliterated above and below the part that had been removed.—*The Lancet*, January 23, 1875.

CHLORALUM.—This substance has lately been analyzed by a Prussian scientific commission. They report that it is not pure chloraluminium, but a mixed product resulting from the action of crude hydrochloric acid upon kaolin feebly heated. The fluid used as a disinfectant contains about 16 per cent. of chloraluminium, the efficient element. The chlorine set free by the decomposition of this compound combines with water to form hydrochloric acid, and the alumina is precipitated. The former deodorizes the ammonia compounds, and the latter carries down the organic substances dissolved or suspended in the foul water, the gelatinous substances excepted. It is, therefore, not a perfect disinfectant, and, in fact, does not equal the sulphate of iron.—*Berl. Klin. Woch.* March 1, 1875.

SUCCESSFUL TRANSPLANTATION OF BONE.—The want of success that has attended previous attempts at transplanting portions of bone renders this case of Prof. Nussbaum's particularly interesting. An officer, in 1870, received a gunshot wound which resulted in a false joint in the middle of the right ulna. The fractured ends were connected by a thin cicatricial cord. The functions of the limb were seriously impaired, notwithstanding the integrity of the radius. To relieve the deformity, the following operation was done, the age of the patient at the time being twenty-four: The false joint was laid bare, and the cartilaginous ends of the bones, which were pointed, together with the false ligament, were removed by strong scissors. The upper part of the ulna was then sawed half across about two inches above the end of the bone, and the upper piece, together with its periosteum, split off with a hammer and chisel. This was so managed, however, as to retain a small bridge of the periosteum for the nutrition of the bone. Finally, the detached piece was so placed in the vacant space that its upper surface was now external, its lower internal, and its outer superior. The fatty and indurated soft parts were divided so as to set up an inflammatory reaction, the bleeding checked by a stream of carbolized water, the wound closed by sutures, and a fenestrated plaster-of-Paris bandage applied. One small spiculum of necrosed bone subsequently came away. The patient made a perfect recovery, so that in the following year he had such full use of his arm that he was appointed to a regiment.—*Aerztl. Int.-Bl.*, Feb. 23, 1874.—*Allg. Wien. Med. Ztg.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, April 17, 1875.

PRELIMINARY EDUCATION.

EVERY little while, we hear it urged from different quarters that one of the principal means of advancing medical education is to insist upon preliminary education. No one doubts the necessity of such a measure. All sorts of plans have been proposed to enforce it, but experience has shown that they sadly lacked the practical element which should insure their successful accomplishment. We are willing to say, at the very commencement of our remarks upon the subject, that we are not aware that we have any original ideas to advance. Our main desire is to discuss the matter from a general aspect, more for the purpose of ascertaining how we stand, what progress we have made during the last few years, and what are our prospects for the future. We all know what strenuous endeavors have been made by the American Medical Association to force the whole question of medical education upon the attention of the profession. There was, indeed, an earnestness of purpose on the part of all the gentlemen who interested themselves in this discussion not to be misinterpreted. No one can say that any pains were spared to reconcile all the conflicting interests of the different medical institutions, or that every feasible compromise was not made to agree upon some general plan of reform which should be agreeable to all. That all such efforts signally failed is a matter of history. The convention of medical teachers, formed for this very purpose, after an existence of three years, finally expired without accomplishing anything more than the adoption of some resolutions, which very few heeded, and which still fewer respected.

The general discussion of the subject was attended with some good result. The presentation of the facts of the case forced the conviction upon all that some radical reforms were necessary. How to accomplish them was, however, a problem which, with the exception of one or two Colleges, none cared to solve.

The subject of preliminary education was one of the principal reforms agitated; indeed, around this centred all the others. As far as resolutions are concerned everything has been done. The trouble has been that no College or Society has seemingly been influenced by them one particle. The most recent resolution, and the one now in full force regulating preliminary examinations, was passed by the American Medical Association within the past five years. It provides that no physician shall allow any student to enter his office without a certificate from the censors of the County Society that the said student has passed a satisfactory preliminary examination. This resolution has been adopted in substance by the Medical Society of this State, and, for all we know to the contrary, by many other similar organizations throughout the country. A most excellent regulation, but, as we have seen by practical experience it is a dead letter. We should like to inquire how many of the County Societies have complied with these commands. As far as we have been able to ascertain, there has not been more than three or four such Societies throughout the State which have not subjected themselves to discipline in this respect. Although the law has been in force in this State for three years, not a single member of a County Society has been brought to account. If it be possible that all the students who have entered the offices of the different medical men throughout the State, were above the requirements of any preliminary examination, we are ready to admit that the law answers its purpose. Even if it were possible for the censors to examine all the applicants, all their efforts would be nugatory unless the Colleges supported their decisions. That this is not so, we all know.

This fact carries with it a very important suggestion, which although it is not new, deserves consideration in this connection. The Colleges should take upon themselves the enforcement of the resolution. They are the only authorities which can agree upon a required standard, and the only ones who can practically exercise any power in the premises. But with the exception of one or two institutions, no effort whatever has been made in this direction. The rivalry of the different schools has almost everything to do with this. In fact, such is openly asserted by the schools themselves. All admit that a preliminary examination should be necessary, and yet they place themselves in the anomalous position before the profession of acting, for mere policy's sake, directly opposite to their convictions. They call themselves learned institutions, capable of educating men for a profession, and yet virtually say that any preparation for the study of that profession is unnecessary. There is no use, however, of repeating worn-out arguments to prove the absurdity of the position assumed by the colleges. The best that we can hope is, that the very falsity of this position will in the end work its own solution. It must come to this if we ever expect to bring our students up to the requirements of a first-class medi-

cal education. By and by it will be as impossible for any medical student who is without a sufficient preliminary education to pursue his studies, as it now is for any one who should presume to take an academic course who is ignorant of the rules of the Latin and Greek grammars. When this time comes we may expect some change in the policy of our colleges, but until then all the efforts of the American Medical Association, the State Medical Societies, all the resolutions which are in force, or may be put in force, will amount to nothing.

A MATERNITY HOSPITAL FOR NEW YORK.

With the very laudable intention of preventing mortality among lying-in women the maternity wards of Bellevue were abolished and a transfer made to Blackwell's Island. At present the upper wards of Charity Hospital are used for lying-in purposes. But what we have gained in one particular we have lost in another. There is no doubt that the mortality may be lessened by the occupation of new wards and by the comparative immunity from those conditions of hospitalism which has made Bellevue somewhat famous, but Charity Hospital is altogether too inaccessible. The maternity wards of Charity may be models of convenience and comfort, but of what avail are they in these cases of emergency which are constantly occurring in a large city? It is true the Commissioners have provided a room in the dock house for the reception of cases requiring immediate attention, but this is so inadequate to the necessities of the occasion that it offers the strongest possible argument for some more elaborate arrangements. The boat makes but three trips daily, and lies at the dock for twelve hours continuously. During the night no trips are made. If a patient happens to fall in labor at odd times, she has either to be confined in the dock house or on board the steamboat, and practically speaking this is all the accommodation which the great City of New York can afford to women in labor who cannot wait to be transferred to Charity. We have no objection to a well-appointed maternity at Blackwell's Island, but as most of the patients come from this city, and a goodly majority of them are liable to fall suddenly in labor, we think some sort of a branch establishment here would hardly be out of place. We understand the Commissioners of Charity and Correction have appointed a committee to take the matter into consideration.

THE MEDICAL DEPARTMENT OF LIFE INSURANCE.

VARIOUS reasons have made it expedient for us to discontinue the publication of a separate department devoted to questions bearing upon life insurance, and the supplementary pages of this number contain, therefore, the last of the series. In future numbers we shall arrange the papers and items of this nature under the

usual headings; and we trust that the change will not render THE RECORD less valuable to those who are especially interested in this department of medicine.

Reviews and Notices of Books.

LECTURES ON CLINICAL MEDICINE. By A. TROUSSEAU, late Professor of Clinical Medicine in the Faculty of Medicine, Paris; Physician to the Hôtel Dieu, etc., etc. * Translated from the third revised and enlarged edition by Sir John Rose Cormack, M.D., F.R.S.E., Fellow of the Royal College of Physicians of Edinburgh, etc., and P. Victor Bazire, M.D., Assistant Physician to the National Hospital for the Paralyzed, etc., etc. Complete in two volumes. Philadelphia: Lindsay & Blakiston. 1873.

THE London edition of this work was published in five volumes, the first one consisting of twenty-three selected lectures, with notes by Dr. Bazire. In the present edition these lectures are published in their regular order, and the notes by Dr. Bazire are omitted.

These volumes contain the sayings of one of the most profound and eloquent teachers of clinical medicine the world has ever seen, and they should be found in the library of every medical man who desires to study disease as it presents itself at the bedside of the patient. As one reads, he becomes absorbed in wonder at the purity of expression, the accuracy of description, the precision in noting symptoms, and the depth of knowledge evinced by this acute observer; and yet elegance of diction has not impaired veracity, nor brilliancy dazzled perspicuity. Issuing this masterly treatise in two volumes has brought it within the reach of all, and the medical practitioner can hardly afford to forego the pleasure and profit of consulting it while pursuing his daily avocation.

It is not within the scope of this note to give any analysis of the contents of this work, for the profession is already cognizant of its real worth. The present edition is well printed, and presents a creditable appearance.

DENTAL PATHOLOGY AND SURGERY. By S. JAMES A. SALTER, M.B., F.R.S., Member of the Royal College of Surgeons, and Examiner in Dental Surgery at the College; Dental Surgeon to Guy's Hospital. New York: Wm. Wood & Co. 1875.

THIS work is a compilation of the author's former essays and papers. As a general practitioner of surgery he recognized the neglected field of dental surgery, enters it, and we have in these pages his twenty-three years' experience. This is the standpoint from which all specialties (dentistry included) should start.

The volume contains twenty-eight chapters. The first and second chapters are devoted to the general anatomy of the teeth and their functions. Then follows abnormalities of the dental organs, as to shape, number, size, and position. The chapter on new-formed dentine is quite interesting—should like to have seen it turned to more practical value, as by proper treatment of the dental pulp that has been reached by caries, a deposit of osteo-dentine would fill up the breach made by decay, and the pulp and tooth saved.

The chapters on congenital defects of structure and form, caries, mechanical injuries, we pass over. The author's terms tooth necrosis as applied to a tooth that

has lost its dental pulp. The writer is inclined to believe that tooth necrosis is better applied to a tooth that has lost *all vitality*, both periosteal (peridental) and pulp. Otherwise it would be necessary to state whether it was death of the dental pulp or the peridental membrane, or both. Do not think that the author's local treatment of inflammation of dental pulp amounts to much as a general thing. The dental pulp receives its blood-supply from intermaxillary vessels, and general treatment is often necessary. Periodontitis may be relieved by local treatment. On death of the dental pulp it is not always necessary to remove the tooth, as the author advises, but extract the dead pulp before decomposition sets in, and fill the pulp chamber.

The chapter on odontomes is a valuable one, and well illustrated by interesting cases. Epulis, referring to position, and not to structure (*επι*, upon; *ουλα*, the gums). Why, then, give this name to one of a class of tumors on the gums? Name all tumors according to their pathological structure, and we get at the truth at once. We are compelled for want of space to pass over many interesting chapters, but must say a word on the chapter devoted to affections of the nervous system. It is excellent, and every general physician and surgeon would save themselves many blunders in diagnosis by following out the instructions there given.

The work is a good one, and we commend it to the profession, and know that they will be instructed by its perusal. The illustrations are mostly original, and are well executed.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 10th, 1875.

DR. F. DELAFIELD, President, in the Chair.

TUMOR OF OESOPHAGUS.

DR. SATTERTHWAITE, on behalf of the Microscopical Committee, presented the following report on a specimen of tumor of oesophagus, presented by Dr. E. Mason, at the meeting of Feb. 10th, 1875:

A growth in the oesophagus was referred to me for examination at that meeting. It consisted of a mass of fungous growths, occupying the interior of the oesophagus. The surface of these growths were uneven and lobular, and had a general elevation above the surface of the mucous membrane of about $\frac{1}{4}$ of an inch. They occupied a space about $4\frac{1}{2}$ inches long.

On microscopic examination these growths appeared to arise from distinct centres, probably in the submucous tissue, from which point they branched outwards towards the interior of the tube, as could be seen by inspection with the naked eye.

Microscopically, the tumor was made up principally of cells having an epithelial nature and packed closely together, and forming branching cylinders, which latter were often seen on cross section, and were round. The appearance thus presented was often like that of an acinous gland. The cellular bodies were large, some measuring $\frac{1}{1000}$ of an inch in their greatest diameter, and some even more. They contained large oval or irregularly quadrangular nuclei. When these cells were isolated their general form and shape corre-

sponded with those found in the ordinary varieties of cancer, such as are seen elsewhere. It is true that when seen in position the cells arranged at the periphery looked as if they were cylindrical; but when they were separated it was rare to find them of that character. The shape appears to depend in a great measure on the way in which they were crowded together. Towards the centre of the cylinders the cells were not compressed so tightly together in many cases, so that they were removed during the process of preparation, making the resemblance they bore to acinous glands more striking.

There were some points, but only a few, where there appeared to be collections of cells nested together, which assumed the coloring matter very sparingly. Sometimes, too, there were one or two cells among the other cells which did not color, perhaps owing to their being old and horny. There were, however, none of the large collections of cells, such as are seen in the epitheliomata of the lip, and especially of the vulva. The epithelioid masses were surrounded by a variable amount of the ordinary form of fibrillated connective tissue. The appearance would indicate, therefore, in my opinion, that we have to do with a carcinoma, such as is generally found in other situations.

URETHRAL CALCULUS.

DR. JANEWAY exhibited a urethral calculus, one-half of an inch in length and a quarter of an inch in breadth, removed by operation from a boy, four years of age. His mother stated that during the year previous he had frequent crying spells, apparently occasioned by severe colicky pains. He then contracted the habit of pulling on the head of his penis, for which she had frequent occasion to punish him. His troubles culminated in an attack of retention of urine, which having lasted for two days, Dr. Janeway was called in. On separating the edges of the meatus urinarius the end of a calculus was seen. A uterine probe was passed into the passage, with a view of relieving the bladder somewhat, and of preparing him for the subsequent extraction of the stone. This latter operation necessitated the enlargement of the meatus, which was done by slitting it open. The calculus was made up of uric acid.

DISSECTING-ROOM SPECIMENS.

DR. JANEWAY also presented several specimens, removed from dissecting-room subjects, and were consequently without histories. The first of these consisted of an impacted fracture of the neck of the femur, at the point of junction with the neck and shaft of the bone, showing a new growth around the inter-trochanteric line. There was a shortening of a little less than an inch. The patient was a female, aged about sixty years.

The second specimen showed ankylosis of the knee-joint, with slight subluxation backwards. The third specimen showed bony ankylosis at the elbow. The last was a series of specimens removed from a woman, twenty-five years of age. They consisted of the bones of the extremities, showing a remarkable disposition to form exostotic spiculae.

FRACTURE OF BASE OF SKULL, WITH TARDY SYMPTOMS.

DR. E. MASON exhibited a specimen of fracture of the base of the skull which was interesting in a clinical point of view. The patient was thirty years of age, a clerk by occupation, who was admitted into Bellevue Hospital Dec. 29th. He had no history, and presented the appearance of a person suffering from intoxication. He was comatose and had stridulous breathing. On examining his head no mark of any

injury could be discovered. In the fossa of each ear there was a clot of blood, which was wiped out, and no further hemorrhage occurred. There was no ecchymosis of the eyelids or anywhere else. There was no paralysis, and the pupils were perfectly natural. He vomited the night he came into the hospital, and the vomited material had the odor of alcohol. On the third day afterwards he vomited a material blackish in color but of the same smell. At this time, his coma having disappeared a few hours after entrance, he complained of pain in his head, and particularly in the region of the ear. He was treated with bromide of potassium for seventy-two hours. His consciousness was of short duration, gradually fading away into semi-consciousness, and finally into coma again, which latter condition dated from the 3rd of January—the fifth day after admission. There was no marked change in his symptoms until January 5, with the exception that he was growing weaker. He then became violently delirious, requiring restraint. On the eighth day after the injury the left pupil was considerably more dilated than the right, although both responded to the light. This was the first time that any irregularity was noticed. At that time also he had a stronger grip in the left hand than in the right. His pulse was then 104 and his temperature 101°. Previous to that date his pulse was not above a hundred nor his respiration above twenty—at one time it was as low as sixteen.

On the evening of the eighth day his symptoms markedly improved, and he became quite intelligent. On the tenth day, for the first time, there was a watery discharge of cerebro-spinal fluid from both ears. Then a diagnosis of fracture of the base of the skull appeared to be well founded. On the twelfth day after the injury all the symptoms became much worse, and for the first time his urine and feces passed unconsciously, and he gradually failed until the sixteenth day of the injury, when he died.

The autopsy was made twenty-four hours after death. The scalp presented no appearance of injury upon its surface. The temporal muscle of the right side was found infiltrated with dark coagulated blood. On turning down the scalp no sign of fracture of the skull was seen. The dura mater was firmly adherent. The other membranes of the brain were cloudy, while the sinuses were much congested. There was a spot of softening of the brain (1 inch by 2½ inches) on the inner surface of the middle lobe of the cerebrum.

On removing the brain an extensive fracture at its base was noticed. The line of fracture extended through both petrous portions of the temporal bone, and also through the ethmoid. The point of interest was, that a patient with such an extensive and serious fracture should have been so long without its usual symptoms, and that with such a fracture and separation of the ethmoid there should not have been a discharge of blood from the nostrils.

ENCEPHALOID DISEASE OF BONES OF HEAD.

DR. KIPP, of Newark, presented a specimen of the above with the following history:

L. K., a cachectic-looking woman, 47 years of age, was suddenly taken with severe pain in left side of head about six months before her death. The physician whom she consulted at the time considered the case as one of neuralgia of the trifacial nerve, and administered subcutaneous injections of morphine, which failed, however, to give her more than temporary relief. Some months later she sought advice from another physician, who found the left eye somewhat pro-

truded and blind. Two months before her death she came under my care. The pain in the left eye and the left side of head was excruciating. Vertigo was present at all times. There was no nausea or vomiting. With the exception of partial loss of memory, her mental faculties appeared unimpaired. There was complete paralysis of upper lid of left eye. The protrusion of the eyeball measured between 2 and 3 lines. The lower portion of the ocular conjunctiva was edematous, and protruded through the palpebral fissure. The eyeball, which was of normal size, was entirely immovable and devoid of sensation. The cornea was hazy in its centre; its periphery was opaque. The pupil was dilated and did not respond to light. With the ophthalmoscope only a dim, red reflex could be obtained. The details could not be made out. The eye was unable to distinguish a bright light from darkness. The tension of the globe was somewhat diminished. An examination of the left nostril revealed great swelling of the lining membrane, especially in the upper and posterior part. A distinct tumor could not be discovered in the nose. In the left temporal region there was an ill-defined swelling.

The patient, who had been hard of hearing on both sides for many years, was now totally deaf in the left ear. The external meatus was so much swollen that no examination of drum head could be made. The right side of jaw and head presented no abnormality.

Believing the case to be one of malignant disease of sphenoid bone, I sent the patient to the German Hospital, Newark, where she remained until she died. The pain in the head and eye was so excessive that even the largest doses of morphine failed to give her much relief. During the last four weeks of her life she was more or less delirious day and night. Her memory appeared entirely lost. Her appetite remained good to the very last. There was no perceptible increase in the protrusion of the eyeball during the time she was under my observation. The tumefaction of the lining membrane gradually increased to such a degree as to cause almost total occlusion of the nostril. The swelling in the temporal fossa was, at the time of death, about twice as large as when first seen. During the last month there was also observed swelling of the left parotid and of the post-auricular and submaxillary glands. The patient became comatose four days before her death. Two days previous to her decease, a profuse discharge of pus took place from both nostrils. The right eye was last examined with the ophthalmoscope about three weeks before her death, when it was found to be normal. With regard to the acuity of vision and hearing of the eye and ear of the right side, during the last month of her life, no positive information can be given, as her mental condition precluded a thorough examination.

The autopsy was made forty-eight hours after death. The membranes of the dura mater were dry, but much congested. In consequence of the adhesion of the dura mater, the brain was removed with difficulty. After the removal a tumor was found in the middle fossa, the dura mater being adherent to the anterior, middle, and posterior portion of the latter. In this membrane were several white, opaque points, which were likewise firmly connected with the brain substance. The origin of the tumor could not be made out. The growth involved the body of the sphenoid, as well as the large and small wings of the left side; also the temporal bone. The disease found its way through the larger wing of the sphenoid, and appeared under the temporal muscle. The walls of the orbit were almost totally destroyed, the orbit itself being filled with encephaloid material. The sheath and sub-

stance of the optic nerve were likewise filled with the material, as was also the retinal tunic. This deposit extended only as far as the sclerotic. The nasal cavity was filled by the infiltration. There was also destruction of the petrous portion of the temporal bone. The tumor also occupied the antrum of Highmore. The growth was cancerous in character, and was composed of cylinders of epithelium, separated by intercellular substance.

DR. DELAFIELD thought that the disease originated in all probability in the antrum.

On motion, the specimen was referred to the Microscopical Committee.

TRISMUS NASCENTIUM.

DR. LEWIS SMITH exhibited a specimen of trismus nascentium. On the 27th of February he was asked to see a baby, at that time seven days old, and which had been sick since the day previous. The family lived in a damp and ill-ventilated wooden tenement in the suburbs. Dr. S. made only one visit, but there was no mistaking the nature of the disease. The mother stated that she had observed nothing unusual in the condition of the child up to the commencement of the disease, with the exception that it had diarrhoea since it was two days old. The number of evacuations varied from six to eight in the day. The disease had commenced with drowsiness, and when the child was aroused it was more than ordinarily fretful. At the time he saw her the tetanic spasms occurred every two or three minutes even when not disturbed. The cord had fallen off the day previously, the umbilicus looked somewhat inflamed, and pressure upon it with the finger produced the spasms. The same condition of things was induced by a similar pressure on other parts of the body. The pulse was 164, and temperature 100°, and the respiration 60 during the intervals of the spasms. During the paroxysms there was a great lividity of the surface, and the muscular rigidity was so great that the child was as rigid as a stick. Death occurred before Dr. Smith had an opportunity to see the case again.

The autopsy was made twenty-four hours after death, assisted by Dr. Heitzmann. The body was somewhat yellow in color. The pupils were equal and somewhat enlarged. Abdomen distended. The umbilicus showed a sore ring, which was covered with a crust. The extremities were rigid. The thyroid gland was small, and the mucous membrane of larynx and trachea was moderately injected and contained mucus. The pleura was dotted with purple spots the size of a pin's head. The lungs were hyperemic, and in many portions presented diffused hemorrhagic infarctions. A few lobules in the left lung were the seats of atelectasis. The thymus gland was unusually pale. The pericardium contained a few drops of hyaline serum. The heart was contracted. Beneath its posterior sulcus were hemorrhages, confluent in character. The cavities of the heart contained soft clots, as did also one of the umbilical arteries. Peritoneum moderately injected. Liver soft and hyperemic—blood without pus in the ductus arantii (venous). The gall-bladder was large, and contained pale yellow bile. No hepatitis. Spleen soft, and reddish brown in color. Stomach moderately enlarged, with mucous surface pale. Intestines distended with gas, and the mucous membrane injected, containing mucous fluid matter. Kidneys—cortical substance pale, but medullary portion hyperemic; infarctions of urates in pyramids. Bladder contracted and empty, and mucous membrane pale. Lymphatic glands of mesentery enlarged, and of a dark grayish-

red color. The brain presented the usual appearance at that age, with the exception that there was intense passive congestion of the membranes.

DR. SELL stated that he had prepared a specimen of fluid discharged from a mammary cyst; but as by an accident, since he came to the meeting, the vial containing the said fluid had capsized, and an opportunity of gaining some information from the Microscopical Committee was lost.

PYOPERMINEPHRITIS.

DR. JANEWAY, in the absence of Dr. Polk, presented the following history, with the accompanying specimen:

Jas. Fogarty, 32, S. Ireland, porter, admitted Dec. 26th, 1874. Family history unimportant. Habits intemperate. Had syphilis. About five years ago patient was troubled by his first symptoms; frequent desire to micturate (some ten or twelve times daily). Was treated for cystitis by injections of nitrate of silver, and after this became worse, and legs œdematous at intervals. Treated then for Bright's, and was relieved as regards symptoms. Afterwards became worse, and was admitted here.

On admission patient well nourished; legs œdematous; passes water more frequently and a larger quantity than normal; urine acid; sp. grav. 1.013; albumen. Ord. diuretics, causing urine $\frac{2}{3}$ 110 to be passed; œdema diminished.

Jan. 24. Passed $\frac{2}{3}$ 112. Jan. 25. Patient complains of lumbar pain for some days past, growing more severe; blister applied. Feb. 12. Patient complains of increased and throbbing pain of left kidney; and examination shows a fluctuating circumscribed tumor, about five inches diameter each way, and shown to contain pus by hypodermic; urine $\frac{2}{3}$ 102, loaded with albumen, acid, sp. grav. 1.014; opium gr. ij. given. Feb. 13. Incision two inches and a half long, four inches from spine, made through lumbar aponeurosis, and pus came out forcibly $\frac{2}{3}$ 36; finger could not feel bottom of cavity thus opened. Feb. 15. Patient did well, and improved afterwards, and passed $\frac{2}{3}$ 38 second after operation. P. 100, R. 14, T. 100 $\frac{1}{2}$ ° A.M.; wound discharges freely; patient eats fairly and is comfortable. Feb. 17. Discharge of wound less; urine $\frac{2}{3}$ 50. Feb. 24. Urine $\frac{2}{3}$ 84, sp. grav. 1.011; P. 108, R. 18, T. 98 $\frac{1}{2}$ °. March 5. Passed urine $\frac{2}{3}$ 72; P. 120, R. 18, T. 101° A.M. March 8. Passed urine $\frac{2}{3}$ 58, sp. gr. 1.013; P. 120, R. 18, T. 99° A.M. March 9. Patient has less appetite; had a chill, and is doing badly; P. 138, R. 24, T. 100° A.M. March 10. Patient died to-day.

Autopsy.—Right kidney weighs $\frac{2}{3}$ 18, fatty, waxy, and interstitial change; left kidney enlarged, surrounded by fatty tissue, the result of fatty degeneration of the cortical substance. Pelvis and calices enlarged and containing pus; sinuses communicating with cellular tissue surrounding the kidney, and a general matting together of the adjacent tissues; pus being found in the crus of the diaphragm and also in the substance of the dome of the muscle.

The cavity communicating with the wound in lumbar region was pretty free of pus. Empyema of left pleural cavity occurring secondarily. Ureter (left) entirely impervious and thickened, and much bound by tough adhesions, and no opening into bladder palpable. Bladder thickened; remains of an old stricture in membranous portion of urethra.

DR. HENRY F. WALKER has been appointed to fill the vacancy in the surgical staff of Bellevue Hospital caused by the resignation of Dr. Ernst Krackowizer.

New Instruments.

FLEXION STRAIGHTENER AND DILATOR.

By ALEXANDER S. HUNTER, M.D.,

NEW YORK.

This instrument—the mechanism of which will be readily understood by referring to the cuts—offers advantages when used either to overcome uterine flexions or to effect the dilatation of the uterine canal, which may be stated as follows:

First.—Its peculiar point, *because of* its short curve, is compelled to traverse the *convex* instead of the *concave* wall of the flexion, and therefore, in the lesser flexions, it does not impinge against and become obstructed by the concavity of the flexed wall, as do the points of the other instruments thus far devised for this purpose. To overcome the more-pronounced flexions, this curve serves a like and even more useful purpose. In this latter class of cases the instrument may be used in the following manner.

Having placed the patient under the influence of an anæsthetic, draw down and secure the uterus with a tenaculum. Now pass the point of the instrument up to the obstruction, with its longer finger opposed to the concavity of the flexion, slightly separate its fingers, and after allowing them to so remain for a short time, bring them together; the point will now pass still farther on in the canal, and by patiently repeating this process the object sought may generally be attained.

An easier, more conservative, and therefore better way to accomplish the same end in this latter class of cases, is to first dilate the flexed canal without straightening it. To accomplish this, I use flexed tents of laminae of *small* size, which have been soaked in an aqueous solution of carbolic acid, and

which have been compelled to maintain while trying the required curve; one, two, or more of these may be introduced without difficulty, for there is less resistance to the introduction of a tent in sections than as a whole. Other sections may be added to those already inserted after they have become dilated; the patient being in the meantime in bed and under the influence of opium.

Again, the curved point of this instrument not only serves to facilitate its introduction in cases of flexions and cervical constrictions, but when inserted this same point opposes in the most satisfactory manner the concavity of the canal, and prevents the injury which might otherwise result to the organ when the fingers of the instrument are forcibly separated; further, while the presence of this projecting point within the uterus can, under no circumstances, prove objectionable, it may serve still another purpose in preventing dilatation too near the fundus.

Secondly.—The straight fingers of the instrument, together with their straight handles, render it capable of effecting dilatation in the *anterior posterior direction*. Does it not follow, therefore, that it is capable of straightening a flexion?

Thirdly.—As a dilator it is also easily introduced, from the fact that its fingers are but $\frac{1}{8}$ of an inch in diameter, and also from the fact that its point follows and closely hugs the *convex*, and therefore does not impinge against and become obstructed by the *concave* wall of the canal. The fulcrum and lever speculum,* if the uterus be either high up, flexed, or anteverted, will also facilitate the introduction of this instrument.

Fourthly.—Its capacity, notwithstanding its slender fingers, to effect dilatation, is secured by the *close* proximity of the power to the resistance.

Fifthly.—Its elastic handles secure for it an elastic pressure with which to overcome flexions or cervical constrictions, or if it be desired to employ an unyielding force, this can be done by the use of the screw at the side of the handle. The same screw may be used to so change the direction of the fingers of the instrument that they will not only dilate the external and internal *os equally*, but either, more than the other, at pleasure; again, the elasticity of its handles enables us to estimate the force that is being exerted.

Finally.—The straight fingers of the instrument, together with their straight handles, enable us to effect dilatation in any direction, therefore the points of bearing can be *shifted* so that the prolonged pressure on any given point may be avoided, and after the dilatation of the canal has progressed sufficiently to admit the gloves, which are then to be added to the fingers of the instrument, the pressure will be still further distributed, as well as its capacity to effect dilatation increased. A second and larger pair of gloves are also furnished, by means of which the cervix may be dilated to the extent of an inch in diameter.

This instrument, and also the speculum above referred to, are made by Tiemann & Co., of this city, to whom I am grateful for their patience and courtesy, as well as for the perfect execution of my design.

Medical Items and News.

A BRITISH DENTAL ASSOCIATION.—The last number of the *Monthly Review of Dental Med. and Surg.* contains a proposition for the formation of a British Dental Association. It is proposed to assimilate its character and constitution to those of the British Medical Association, and to hold the meetings at the same time and place as those of the latter.

PROFESSOR PAJOT, who has been prevented by over-fatigue from lecturing for the past two years, is to resume his functions in the Paris School of Medicine.

THE LONDON MEDICAL SCHOOL FOR WOMEN.—It is said that eighteen young ladies have been studying medicine in Henrietta-street School of Medicine during the session now closing.

M. HENRI ROGER, the highly esteemed and well-known "children's doctor," who has for many years been attached to the Children's Hospital of Paris, has, by the inexorable law of age, been obliged to relinquish his office, he having completed his sixty-sixth year. He is succeeded by M. Blachez.

* The length of the upper blade of this speculum has been reduced, while the upward curve of the open extremity of the under blade (described in the 214th No. of this Journal) has been increased, rendering it even more efficient than before in overcoming the utero-vaginal angle.

A, A, Fingers. B, B, Gloves of hard rubber. W, Wedge which separates the fingers.

SUCCESSFUL REMOVAL OF GOITRE.—Professor Lister lately operated successfully at the Edinburgh Royal Infirmary, in a case of goitre affecting both sides of the thyroid body. Before proceeding to remove the tumor, the operator ligated the superior and inferior thyroid arteries, which almost entirely prevented hemorrhage.

The "MISSOURI CLINICAL RECORD" has changed its title to the "*St. Louis Clinical Record*."

HOSPITAL APPOINTMENTS.—The following appointments have been made by the Commissioners of Public Charities and Correction:—

Reception Hospital, Ninety-ninth street.—Clifford M. Steele, M.D., appointed senior assistant physician; Frank B. Bennett, M.D., appointed junior assistant physician, to fill vacancies.

Nursery Hospital—Peter John Popoff appointed assistant physician, to fill vacancy.

Park Reception Hospital.—Thomas H. Manley, M.D., appointed junior assistant physician.

JOHN HUNTER ON OVARIOTOMY.—John Hunter is reported to have said: "I cannot see any reason why, when the disease can be ascertained in an early stage, we should not make an opening into the abdomen and extract the cyst. Why should not a woman suffer spaying as well as other animals do? The merely making an opening into the abdomen would never be followed by death in consequence of it."

AMERICAN MEDICAL ASSOCIATION.—The twenty-sixth annual session of the Association will be held in Louisville, Ky., on Tuesday, May 4, at 11 A.M.

SECTIONS. *Practice of Med., Mat. Med., and Physiol.*: Drs. Austin Flint, Sr., New York, and J. K. Bartlett, Milwaukee. Special Committees appointed to report to this section, "On Meteorological Observations," Drs. J. M. Toner, D. C.; J. J. Woodward, U. S. A.; E. Lloyd Howard, Md. "On Clinical Observation," Drs. N. S. Davis, Ill.; H. A. Johnson, Ill.; J. B. Johnson, Mo.

Obstetrics and Diseases of Women and Children: Drs. W. H. Byford, Chicago, and S. E. Busey, Washington, D. C. Special Committee, M. A. Pallen, N. Y.; L. F. Warner, Mass.; J. K. Bartlett, Wis. "On Unusual Fœtal Presentations," Dr. J. A. Oeterloney, Ky. "On Retroversions of the Uterus in the first Five Months of Pregnancy," Dr. Heaton, Mich. "On the Connection of the Hepatic Circulation with Uterine Hyperæmia, Fluxions, Congestions, and Inflammations," Dr. L. F. Warner, Mass. "On the Relation of Menstruation during Lactation," Dr. S. C. Busey, D. C.

Surgery and Anatomy: Drs. E. M. Moore, Rochester, N. Y.; T. S. Latimer, Baltimore, Md. "On the Treatment of Fractures," Dr. Lewis A. Sayre, N. Y.

Med. Jurisprudence, Chemistry, and Psychology: Drs. Jerome Cochran, Mobile, Ala.; G. A. Moses, St. Louis, Mo.

State Medicine and Public Hygiene: Drs. H. J. Bowditch, Boston, Mass.; H. B. Baker, Lansing, Mich. "On Ventilation of Dwellings, School-houses, and other Public Buildings," Drs. R. C. Kedzie, Mich.; A. B. Stuart, Minn.; R. J. O'Sullivan, N. Y. "On Form of Bill to Establish a National Department of Public Health at Washington," Drs. H. B. Baker, Mich.; H. A. Johnson, Ill.; J. M. Toner, D. C. "On what Legislative Action, if any, can be taken to enforce by Law an Examination of all Persons who enter upon the Practice of Medicine and Surgery, by a State Board of Medical Examiners," Drs. Foster Pratt, Mich.; S. G. Amor, N. Y.; D. W. Yandell, Ky.

*Papers appropriate to the several sections, in order to secure consideration and action, must be sent to

the Secretary of the appropriate section at least one month before the meeting which is to act upon them. It shall be the duty of the Secretary to whom such papers are sent to examine them with care, and, with the advice of the Chairman of his section, to determine the time and order of their presentation, and give due notice of the same. . . .—By-Laws, Art. II., Sect. 5.

The following Committees are expected to report: "On Cultivation of the Cinchona Tree," Dr. L. J. Deal, Pa. "On some Diseases peculiar to Colorado," Dr. John Elsner, Col. "On American as compared with Foreign Winter Cures," Dr. H. R. Storer, Mass. "On Railroad Injuries," Dr. W. F. Peck, Iowa. "On Proper Legislation to Prevent the Spread of Syphilis," Dr. S. D. Gross, Pa. "On the Use of Pessaries," Dr. John Morris, Md. "On Cystic Degeneration of the Kidneys," Dr. J. A. Oeterloney, Ky. "On the Diseases of Minnesota and the Northwest," Dr. D. W. Hand, Minn. "On Prize Essays," Dr. John Davis Jackson, Ky. "On Necrology," Dr. S. C. Chew, Md. "On Rank of Medical Department of the Army," Dr. J. M. Toner, D. C. "On International Medical Association," Dr. J. M. Toner, D. C. "On Memorial on Dr. Henry Miller, deceased," Dr. S. D. Gross, Pa. "On Memorial on Dr. George Mendenhall, deceased," Dr. J. A. Murphy, Ohio.

The following amendments to the Plan of Organization are to be acted upon:

By Dr. H. B. Baker, Michigan:—

"The officers of the several sections shall be nominated by the section in and for which said officers are to serve."

By Dr. Adams Jewett, Ohio:—

"The permanent members shall consist of all those who have served in the capacity of delegates, and of such other members as shall have received the appointment by unanimous vote, and of all others who, being members in good standing of any State or local Medical Society entitled to representation in this body, shall, after being vouched for by at least three members, be elected to membership by a vote of at least three-fourths of the delegates in attendance, and shall continue such so long as they remain in good standing in the body of which they were members when elected to membership in this Association, and comply with the requirements of its by-laws."

THE PHILADELPHIA *Medical and Surgical Reporter* says: "The paper on Nitrate of Silver, before the New York Medical Society, referred to in the *Reporter*, February 27th, p. 169, should have been credited to Dr. Marion Sims, not Dr. Mary Jacobi." We are somewhat curious to know the source from which the *Reporter* gets this bit of information. We have always supposed that Dr. M. P. J. was quite able to write her own papers as well as read them, and we have yet to learn that Dr. Sims, in addition to his other accomplishments, is an expert in histology and microscopy; or that he is in the habit of writing papers for other people to read.

Like unto the foregoing is an announcement in the *Chicago Medical Times* of a paper read before the Medical Society of the County of New York, on "The Relation of the Medical Profession to the Delusions of Spiritualism, Animal Magnetism, Clairvoyance, Mind-Reading, etc.—How these should be Detected and Exposed." By Dr. H. B. Sands.

MANSLAUGHTER BY INFECTION.—A woman named Elizabeth Marsden was recently committed for trial in the English courts for having, in her capacity as a midwife, carried the infection of puerperal fever to several

patients, who died in consequence. She appears to have been cautioned by a surgeon against continuing in practice. *The British Medical Journal* of March 13th says, referring to the case of a Mrs. Ingram, whose trial for a similar offence took place a week before: "The precedent is a very stringent one, and, as we pointed out before, if manslaughter by infection became an offence readily recognized and habitually punished by criminal prosecution and conviction, it will undoubtedly behave all medical practitioners, as well as midwives, to move with very great caution; and, unless such prosecutions be regarded with some jealousy, and a sincere regard to all the related facts and consequences, the perils of professional practice will be very largely increased. The prosecution of midwives appears to take place amidst considerable applause; nor ought they to escape any penalty which attaches to ignorance or neglect. It is obvious, however, as we pointed out from the first, that the arbitrary principle involved does not concern midwives only. The editor of the *Edinburgh Medical Journal*, commenting on the case of Mrs. Ingram, illustrates his views thus: 'Down comes the policeman to Sir William Jenner, to tell him to see no more cases of croup for two months, at his peril, as the Coroner hears he has been attending some fatal cases; to Sir William Gull, to give up practice for two months, as he hears he has been attending some fatal cases of scarlatina; to Dr. Farre, to give up practice, because he has been in repeated consultation in a fatal puerperal case; to Sir James Paget, to give up operating, as he is in attendance on a case of erysipelas, and so on.' In these days, when the extent to which diseases are influenced by septic germs and hospital influence is much debated, the vista opened by such prosecutions leads a long way, and is lost in a rather obscure shade."

STATISTICS OF BIRTHS IN MASSACHUSETTS.—At a recent meeting of the Obstetrical Society of Boston, Dr. Draper, who said that he had been recently looking up the statistics of births in Massachusetts, gave the following as among the results of his investigations. Most children have been born in the latter half of the year, and the majority of these in the last quarter. In the last twenty-five years, the period included in the examination, the proportion of males to females born has been as 106 to 105. The births of children of American parentage have decreased from 63.02 per cent. in 1849 to 39.98 per cent. in 1873; the births of children of foreign parentage have increased from 35.96 per cent. in 1849 to 48.24 per cent. in 1873; while those of mixed parentage, one parent being foreign, the other American, have increased during the same period from 1.02 per cent. to 11.78 per cent. Still-born males have been greatly in excess of the females. Of plural births the proportion is constant: 1 to 100. In 1873 there were six cases of triplets. In a discussion which followed, Dr. Chadwick asked if the customs with regard to marriages had anything to do with the time of births. In Vienna the effect of the carnival was very marked nine months later. Dr. Draper said the greatest number of marriages in Massachusetts is at Thanksgiving time, in November, while the smallest number is in March.

THE BIRTHS AND DEATHS IN DUBLIN.—During the year 1874 there were registered in the Dublin registration district, 8,903 births, equal to a ratio of 28 per 1,000 of the population. The weekly average was 171. The deaths registered during the year were 8,190; equal to 26 in every 1,000 of the population, which was also the average death-rate for the preceding ten years. The deaths from zymotic diseases exceeded the

average of the preceding ten years by sixty-three, the number being 1,916, or one in every 43 of the deaths, and 61 in every 10,000 persons living. Scarlet fever, which had been epidemic for the last fifteen months, caused 834, or ten per cent. of the total deaths. Deaths due to fever were 352 in number; to small-pox, 2; whooping-cough, 40; measles, 97; diarrhoea, 203; diphtheria, 44; croup, 113; quinsy, 19; and erysipelas, 49. Bronchitis caused 1,000 deaths; pneumonia, 206; heart-disease, 376, and phthisis, 862.

SOME "ANTI-VACCINATION" DELEGATES recently waited upon a candidate for the House of Commons and asked him whether, if they voted for him, he would support the repeal of the Compulsory Vaccination Act. His answer was: "If you will only vote for me to-morrow, you may all get the small-pox next day if you like," which answer was not considered perfectly satisfactory.

THE INTERNATIONAL MEDICAL CONGRESS will meet at Philadelphia in September, 1876. The profession in Philadelphia have already appointed a Commission, of which Dr. Samuel D. Gross is President, and Drs. Atkinson, Dunglison, and Brinton are secretaries. Invitations will be sent to the principal medical men of the world, and delegates will be received from all orthodox medical societies, credentials being required. The proceedings will consist of papers and discourses upon medicine and medical progress in this country; upon surgery, obstetrics, chemistry, hygiene, medical education, etc. No vote will be taken, nor will discussion be encouraged during the session.

It is said Professor Heschl will probably succeed Rokitsansky at the University of Vienna.

CHLORATE OF POTASH IN THREATENED ABORTION.—Dr. Bruce, in a communication to the Obstetrical Society of Edinburgh, has called attention to the value of this remedy, and he supports his statements by the authority of Inglès, Cairns, Moir, and Keiller. Piccini is also said to have known of several cases in which the chlorate has been successfully used with women who ordinarily failed to reach their full term.—*Gaz. Méd. de Paris*, 12, 1875.

DR. MEREDITH CLYMER, President of the N. Y. Society of Neurology and Electrology, wishes to make some corrections to our report of that Society published in our number for April 10. He writes:—"I am made to say in the report you have published, that 'fully one-third of the cases of nervous diseases I am called on to treat were dependent on some form of genital irritation, and that the other two-thirds were due to blood-poisoning.' What I said was, that of the *functional* disorders of the nervous system which came under my notice, one-third perhaps were due to irritation of the genital organs in the two sexes; the other two-thirds to some form of blood-poisoning. A very essential distinction."—[We make the correction with pleasure.—Ed.]

WEEKLY BULLETIN OF MEETINGS OF SOCIETIES.

Monday, April 19.—Obstetrical Section of the Academy of Medicine; Medico-Chirurgical Society; New York Society of Neurology and Electrology; Pathological Society of Brooklyn.

Tuesday, April 20.—New York Obstetrical Society; New York Dermatological Society; North-western Medical and Surgical Society; Medical Society of the County of Kings; Newark Medical Association.

Medical Department of Life Insurance.

THE RELATION OF SYPHILIS TO HEALTH AND TO LIFE.

By R. W. TAYLOR, M.D.,

PHYSICIAN TO CHARITY HOSPITAL, SURGEON TO THE NEW YORK DISPENSARY, DEPARTMENT OF VENEREAL AND SKIN DISEASES.
(Continued from the March 13th Number of THE RECORD.)

THE heart and its appendages may also be affected by syphilis in such a manner as to compromise life. The chief lesions are:—

Infiltrations into the muscular structure of the heart.

Infiltrations into the pericardium (Wilks and Virchow).

Infiltrations beneath the endocardium, and upon the valves and their appendages (perhaps).

Degeneration of the vessels, arising from the heart, owing to previous inflammation, or perhaps infiltration.

Recent observations by Bälz (*Archiv der Heilkunde*, Feb., 1875) go far to establish the fact that syphilis may induce a hemorrhagic condition, which may eventuate in death. This observer reports two fatal cases, and one in which recovery took place. The question as to their cause was, whether the process was wholly due to degeneration of the capillaries, or whether there was an altered condition of the blood. The latter supposition is the one more forcibly borne out by the details of the cases. We may then in a qualified manner admit that in rare cases a hemorrhagic condition is produced by syphilis, which may prove fatal.

Severe ulcerating lesions and degeneration of syphilitic infiltrations somewhat infrequently lead to death. Thus in some cases of extensive chronic ulceration of the skin, the patients have gradually faded and died from the concomitant exhaustion. Then again, degenerations of infiltrations into the bones have produced a similar adynamic state, which finally was ended by death. In the event of degeneration of osseous syphilitic lesions about the cranium, death may be caused by the implication of the cerebral meninges. Still it is a fact that has twice struck me as being singular, that very extensive and chronic necrosis of the cranial bones (usually the frontal), even with destruction of the dura mater, may continue for years without compromising life. I had under observation, some years ago, a case in which destructive action began ten years previous in the frontal bone, resulting in a loss of the entire thickness of the bone for an area of two inches, with a corresponding amount of the dura mater, and yet life was not compromised; and it is probable that the woman might have lived for years longer had not an intercurrent double pneumonia carried her off.

There is a cachexia induced by syphilis which is not well brought out in the books, and it is of much interest. I refer to that breaking up of the constitution which occurs late in the history of syphilis. Its history, in a general way, may be sketched as follows: A man passes through his secondary period without any noticeable severity of his disease; he is not as careful as he should be in following out proper treatment. Later on tertiary lesions of a character perhaps troublesome, but not alarming, cause him to seek advice. He is again partially treated. At this time, or earlier, he begins to experience a general condition of ill-health. He is unable usually to fix upon any particular organ as being involved, and his symptoms are not indicative of any particular disease, or referable

to any one organ. He feels weak, generally has errors of assimilation, which he calls biliousness, or perhaps thinks that his stomach, liver, or kidneys are out of order. A peculiar pallor gradually spreads over the face, and soon it is evident that the patient has some organic visceral disease. This condition may continue and end in death without any one organ more than another seeming to be involved, or the end may result from cirrhosis, or kidney disease, or it may be accelerated by acute intercurrent disease. In the latter condition, the general character of the acute complicating disease is greatly modified—much more so than it would be in a person previously healthy; and the patient succumbs, sometimes unexpectedly to the attendant, usually without the acute disease having assumed of itself such a formidable character, as would seem necessary to involve life. At the autopsy of such a person, though perhaps there may be found considerable fatty development, there is usually a flabbiness of the tissues and in most cases a greater or less state of amyloid degeneration of the viscera. This amyloid degeneration, resulting from chronic generally improperly treated syphilis, may be of a mild character and may involve several viscera, or again it may be concentrated principally in one organ, and the interference with its function may be the cause of the death of the patient. It is well, then, to bear in mind this condition of cachexia or of gradual exhaustion as occurring late in syphilis, as it is one of considerable importance. I am thus particular in calling attention to it, not only by reason of its bearing upon our present inquiry, but also to establish it fully as a morbid entity in direct contradistinction to the cachexia or exhaustion which occurs in secondary syphilis. Between these two states there are great differences, both as to cause, to the question of prognosis, and also as to their susceptibility of cure by treatment. In this connection it is well to allude to the general condition of ill-health which sometimes accompanies affections of the nervous centres due to syphilis. Thus in such persons, having, for instance, optic neuritis, we often observe a coexistent exhausted state and that they are ill able to withstand acute disease.

These are in general the affections or conditions which may be induced by syphilis and which in various ways may cause death with greater or less rapidity. The effect of syphilis varies materially with the age, condition and habits of the person affected, and is more or less profoundly modified by the constitutional state. It may conduce to a clearer line of study to consider here in advance the influence of the disease upon the extreme ages. Syphilis in the young child—I mean a subject from eight to eighteen years—is not, according to my observation and study, necessarily a severe or fatal disease, nor does its existence necessarily portend to the individual a blighted future. On the contrary, I think that cases which I have observed warrant me in stating that the young generally pass through their syphilis without any very serious damage, and that in them there is a marked tendency for the disease to run out early, in other words to be cured. I refer in this connection to children who possess a healthy organism. When they are properly treated their lesions are slight and of short duration, and the disease ends virtually at the secondary period without the supervention of tertiary manifestations. It may be even in such subjects that the early manifestations are very severe, and yet their bearers rally with a marvellous resilience, and finally as it were grow out of the disease. It has occurred to me that perhaps at this age there is less reaction to the virus of syphilis than later on, and that its products do not to o

great an extent increase and multiply, consequently that the disease soon loses its hold. I am here alluding to cases of acquired syphilis in which there was primarily a healthy organism. This subject has as yet not been treated of in literature, hence I am forced to base my statements upon cases which I have personally observed. There are circumstances surrounding the youthful subject, taking of course one from a good class of the community, which are in favor of a mild course of syphilis. There is the absence of any abnormal condition of the system from habits, exposure, etc., etc., and besides this they enjoy hygienic influences which are impossible to the subject of syphilis in later years who has to undergo more or less the confinement of business with the various other cares and vicissitudes of life. When I first reflected upon this subject I was of the opinion that as the organism of the child is immature it would be profoundly affected by syphilis, yet actual examination of cases shows me that there is in such subjects a certain immunity to the action of syphilis. If infected early and then properly treated, it is very probable that such subjects throw off the influence of the disease, and that at maturity they are not very much damaged. I scarcely think that quite such a favorable statement can be ventured upon persons who become syphilitic just about or prior to puberty. The peculiar morphological changes of the system which take place at this period in the economy, seem, judging from the course of syphilis in such, to render them susceptible to a severe attack. At this period—and I think that other observers will coincide with me—there is not that resilience of the system, such as we observe in earlier years. In subjects of this age the disease seems to develop itself to a marked degree, the cell proliferations incident to it are very active and copious; in fact, the lesions are extensive and severe, and there is often noticed an early evolution of those manifestations which are usually confined to the late or tertiary period. As to sex, I think it will be found that women particularly at this time suffer more profoundly than men do. Again, at this epoch there is often to be observed a decided tendency in the syphilitic disease to modify in a menacing manner any morbid predisposition inherited or acquired which the individual may possess. This same modification may be observed in the syphilis of younger persons, but I think that it is most marked at the age of puberty. Space will not permit me to enter into a consideration of the probable causes of this susceptibility, and I shall briefly explain it by saying that as at this time the whole economy is in a very active and in a measure transitional state, and as it is probable that the tendency to cell proliferation generally is then greater, the system is more powerfully affected by the syphilitic action which, as we have already shown, consists in perversions of nutrition, in hyperemia and hyperplasia. Grave as the syphilitic condition may be at this period it need not necessarily lead to a fatal issue. Indeed, we have, at this time especially, urgent necessity for well-regulated careful medication. If subjects of syphilis at this age are carefully treated in the broad sense of hygiene and therapeutics, there need be no fear as to the result. Generally such subjects, though they may pass through a severe ordeal, get well, yet there is at this time, perhaps, more than at any other, need for watchful care on the part of both patient and physician. I shall further on dwell at some length upon the necessity and value of treatment, and I may here say, that in treating patients of both sexes, perhaps I may lay more stress as affecting the female; it is at this time absolutely necessary that a long-continued mercurial and hygienic treatment

should be followed. At this period especially, intercurrent diseases are apt to be severe or to leave serious sequelæ or to prove fatal.

In the aged and in those prematurely old syphilis, in general, to be very much feared. While it may run a mild course in persons between the ages of from thirty to nearly fifty, after the latter period is passed, with some exceptions, its evolution is attended with circumstances of great gravity. There is then super-added to the gradual decay of the system a disease which may prove fatal quickly by inducing inflammations, or by hastening the course of structural organic lesions which otherwise would but slowly develop. At this period especially syphilis may enfeeble the power of resistance of the system, and it frequently stamps upon acute intercurrent disease a malignity not observed in an uncomplicated state. Although these are the general facts there are numerous exceptions, and we see instances in which the aged, becoming syphilitic, seem not to be in a severe manner affected by their disease; but on the contrary they, so to speak, throw it off. Practically applied, our doubts and fears as to the course of syphilis at this time of life should teach us to be very cautious in our prognosis, and to be apprehensive of a severe ordeal. In entering into contact with such parties too much care cannot be exercised, for the reason that we cannot feel certain, even if they pass through the first few years of their disease without much suffering and are then in seemingly perfect health, that they will not be overtaken later on by some affection, more or less remotely dependent upon syphilis, which will cause death. Space prevents the further elaboration of this interesting and important point, therefore I content myself with the somewhat cursory but practical treatment which I have accorded to it, for while it is essential that the critical state of their constitution should be fully taken into consideration, it is necessary to weigh well the general facts presented by the individual instance. Thus a previous unbroken state of health, the absence of any organic disease, the appearance of more than average strength, as shown by fulness of development and firmness of tissue, the non-indulgence in debilitating habits, are conditions which argue in favor of the power in the system of the patient of throwing off the disease.

Before considering the main issue involved in this inquiry, and in order to avoid confusion subsequently, I shall have to consider the influence of inherited syphilis upon life. Now it is well known that owing to various obvious causes inherited syphilis varies very greatly in intensity and in severity of course. The state of the child bears a relation to that of the parents both as to the general condition of the system, and as to the activity of the syphilitic disease. Early and active syphilis in a mother generally induces a severe syphilis in her child. The inherited disease, then, may be such as to kill outright, to severely compromise the existence, or it may be so mild and ephemeral that no malign effect is produced. The practical question involved in this inquiry is, what is the condition of the system and health in maturer life of those who were in infancy victims of hereditary syphilis. The prevailing opinion is that the constitution of such subjects is so profoundly altered that they are in reality incarnations of disease. My observation and experience lead me to take exception to this view. On the contrary, I think that clinical observation will show that infantile syphilis may be recovered from, that the diathesis may be exterminated, and that by a proper course the constitution of the person may be so profoundly modified by careful treat-

ment, medical and hygienic, that no traces of syphilis thereafter will be observed. Further, I think that many such persons will pass through life, even through severe adynamic disease, without their previous serious condition in any way modifying or compromising their existence. It is true, that when born such subjects are, so to speak, saturated with syphilis, still the disease is now so much under control, and our views are to-day so enlightened as to the manner of treating it, as well as our medicines are so powerful in modifying it, that I think that I state but the truth when I say that even the inherited syphilitic diathesis may be cured. If inherited syphilis is to prove fatal it usually does so early in life; in fact, the ordeal induced by the disease is confined to early periods, and if at this time proper treatment is instituted it may be so successful that at maturity such a person would possess a healthy organism. It is certainly true, that victims of hereditary syphilis die in great numbers, still the issue occurs early, and the disease does not in the vast majority of cases leave any sequelæ, or any general condition which in after-life may tend to death. It is astonishing, and I but repeat the experience of every one who has studied this question, what severe forms of syphilis may be observed in the child, and yet under treatment recovery may take place, and later, such children may present no recognizable deviation from health. It certainly must be admitted that the nutrition of some children is so profoundly lowered by inherited syphilis, that they in childhood are miserably weak and sickly. Yet recovery, sometimes seemingly perfect, occurs under these circumstances and the morbid impress is finally thrown off. I am inclined to account for these auspicious circumstances by the facts that young organisms generally are prone to throw off disease, or rather not to offer in their tissues a very favorable soil to the development of syphilitic inflammations and infiltrations, and also that treatment is by them so well borne and productive of such gratifying results. In this connection, an important question is suggested, and one pertinent to our present line of inquiry. It is this: Can hereditary syphilis lay the foundation of a future decay of the system, which manifests itself late in life? In other words, after a hereditarily syphilitic subject has passed through youth and puberty without having suffered from any syphilitic lesion, is he or she liable, by reason of her inherited disease, to develop after maturity a condition of ill-health which might cause death? I am inclined to answer this generally in the negative. There are exceptional cases in which such subjects become broken down about the age of maturity, or during puberty, presenting in some cases, and not in others, syphilitic manifestations. Such subjects are sometimes seen, but compared with the frequency of hereditary syphilitics, I think they may be stated to be very rare indeed. I am disposed to think that the lurking tendency of inherited syphilis is not so long delayed as to the eighteenth or twentieth year, but that under proper circumstances it comes to an end and leaves the organism free. To practically apply this point, should an examiner refuse an applicant of twenty-one years or over, because he or she in infancy inherited syphilis? In general I think that he should not. If such a subject has been healthy during childhood, is then healthy, and possess no visceral lesions, I think that he or she might be considered a fair average risk, and it seems to me that a refusal to enter into relations with him or her would be an act of injustice. It would be well to look rather minutely into the general condition of such a person, yet I think that if he or she had passed

to man's estate without having recently shown any serious deviation from health, there would be no good grounds for refusal.

We are now prepared to consider the condition of a man who is syphilitic, who prior to infection possessed a sound frame, and who might be called robust and healthy. It is very difficult to establish with accuracy the standard of health as it varies within considerable limits, so I shall here discuss the question as to the subsequent effect upon health, by assuming that we are treating of the individuals as we find them generally in the upper and middle classes. Many facts enable us now to say positively that syphilis is curable, the most convincing being that of the occurrence of syphilitic infection a second time; therefore, we are now able to speak in a comforting and assuring manner to our patients, and to dispel from their minds those fearful forebodings and gloomy clouds which in many cases have blighted their future. Yet, though the disease is curable, it requires an effort on the part of the patient to arrive at that happy state. We know that in some exceptional cases syphilis, even untreated, has not passed beyond a mild and short second stage, yet we must not assume this course as being the usual one, but as a great exception. We have already seen that syphilis manifests itself in its essence, so to speak, by congestions and by proliferations of tissue, abnormal and normal. Now in the economy of various persons the susceptibility to undergo these morbid changes varies in very different degrees. Thus in some cases we see, after the disappearance of the infecting or initial lesion, a slight tendency to morbid hyperæmia, with a still slighter tendency to abnormal cell proliferation, whereas in others these conditions are greatly intensified, constituting a severe course of the disease. I had this fact so clearly shown to my mind that I think I may with benefit briefly quote the cases as examples. A man of robust build contracted syphilis, five years ago, which, commencing with a lesion upon the penis in the form of an intense indurated nodule of great size, was manifested by two rather large papules, one upon the forehead and the other upon the abdomen, with a very slight and ephemeral roseola, and a similar hyperæmia of the pharynx. Under treatment these rapidly disappeared, and this man has never since experienced the slightest sickness, nor has he presented any other syphilitic manifestation. I have seen other similar cases. But as a contrast to this picture let us look at his wife. She was a woman of slight build, and of delicate fibre, who, though she never was strong and robust, generally enjoyed good health, never had any pulmonary weakness, nor had her family. She became syphilitic and had a papular eruption during the summer months. In the winter she had, owing to catching cold, a bronchial catarrh, which became very severe, and though she was treated actively and nourished largely upon nutritious food and alcoholics, she did not rally until the spring. At this time rough inspiration over both lungs generally showed that there was interstitial proliferation of connective tissue. During the next summer she was cared for in the most painstaking way, was treated medically and supported by nutritious diet, with alcoholics, and was surrounded by good hygienic conditions, yet she did not fully regain her health. In winter she was early confined to bed with a recurrence of her pulmonary trouble, and she died as a result of that and of exhaustion. After the evolution of the first cutaneous rash she did not present any visible syphilitic lesion except that all of the ganglia were markedly enlarged. I may here say incidentally that I have quite frequently observed that in such cases, or

in those in which visceral lesions occur early, the syphilitic disease does not usually show itself by visible manifestations, in other words that there is a marked absence in such cases of lesions of the skin. I have not seen this fact mentioned by any author. Now these two cases show the extreme limits of syphilitic action and their import is very great. The organism or the tissues of the husband seemed unsusceptible to the proliferation of syphilitic new growths, hence the morbid tendency soon died out. He perhaps might again become syphilitic quite early. In the wife, on the contrary, there was a tendency to reaction, and we find that syphilis produced new tissue in organs necessary to life. In this case it is probable that the lesion was not largely if at all a genesis of gummy granulation tissue, but on the contrary there was an hyperplasia of the lung tissue. Though the tendency to become more or less profoundly affected by syphilis resides in each individual, yet are we able to so modify it that we can assure our patients of a cure, and here is the cardinal point of our inquiry at this stage. In the light of our present knowledge we know that we have two remedies, which, given singly or combined, are capable of curing syphilis. We know now that the malignancy of the disease which was formerly observed has gradually died out, and that of itself it is not as formidable as it was; still, if we read even the category of affections which syphilis may cause, and which may result in death, which I have given, it will be seen that it is no trifling state, but on the contrary one which requires our earnest care and attention. No other state is attended with so many manifestations, nor is death induced under such multitudinous conditions by any other disease. Therefore, though a now comparatively mild affection, it is certainly one not to be slighted or regarded as insignificant. A man presenting himself with syphilis is, as I have a little before said, a medical problem. He has to run a gauntlet of great severity, and his future is certainly much beset with shoals and quicksands. In practice, the future of such persons is to me always a subject of careful study, and by observing the evolution of the disease closely I have arrived at a process of thought, as undoubtedly many others have also, by which I can in a measure pronounce a prognosis. I am inclined to take exception to the dicta as given by many as to the prognosis in syphilis. Thus we are told that a very large, very much indurated initial lesion may be and generally is followed by a severe attack of syphilis. In some cases this certainly is true, but in very many it is not. The case above quoted is an example to the contrary. Again, it is thought that severe ulceration of the initial chancre portends a serious syphilis. In a limited degree this may be true, but as a rule it cannot be relied upon in the least degree. I have seen the most formidable ulcerating, even phagedenic chancres followed by very mild syphilis; others have undoubtedly done the same. It is urged that an early and copious evolution of secondary manifestations generally indicates a grave future state. How often is this true and how much oftener is it false? How many cases do we see in which the secondary explosion, to use a French term, is of the most alarming character, which are subsequently mild, and which never develop late lesions at all. Yet again, the early evolution of lesions of a pustular character is considered by some as of serious omen, and if such lesions show a tendency to ulceration, particularly if it is severe, the climax is thought to be reached, and it is considered absolutely certain that there will be a terrible, perhaps fatal, course of the syphilis. Still clinical observation strips this assertion of its terrors, and shows us that

the lugubrious picture is based upon exceptional occurrences. Finally, as a prognostic sign of bad import, the early evolution of tertiary lesions, particularly if severely ulcerative and very extensive, is by many regarded with great solicitude. Under these circumstances there is need of some hesitation; yet I think I can add this very comforting assurance, that if these lesions are tegumentary they need not be considered as of very great import as to shortening life, though they may be very annoying by reason of the trouble that they give, and the destruction which they entail. As I have said, luckily for the human race, syphilis in general, nay, in by far the greater number of cases, expends itself upon the skin and its appendages, and mucous membranes, and leaves organs essential to life free, hence it may be of great severity and of long persistence, and yet its victim lives. Again, I think I may say, almost as a rule, that where syphilis shows itself in a very malignant manner in the skin, the vital organs happily enjoy an immunity, consequently death does not ensue if we can, under such circumstances, prevent the exhaustion which accompanies this state. I have now taken from you the few points which were considered as being of import in the matter of prognosis in syphilis; you will now justly say, if we have not these, how are we going to form an adequate estimate of the future of a syphilitic? I can, I think, put this matter to you in a very short and practical form, Mr. Editor, and a form which is not liable to the numerous qualifications which attend the other prognostic points. *Given a case of syphilis, in a previously healthy person, even of considerable severity in its first and second stages, if it is properly treated throughout the first two years, or perhaps two years and a half or three years, by an active mercurial treatment at first, followed either by iodide of potassium alone, or in combination afterwards, it can almost positively be said that the chances are ninety or ninety-five in a hundred that the future of that man will be as free from disease as he would be if not syphilitic.* This is strongly put, but not too strong; the assertion as here given is warranted by clinical observation, and is supported by the evidence of high authorities. It must be understood that, during the first three years at the utmost, generally I think two years, we will say, the patient is to, from time to time, undergo treatment, to be continually watched, to be guarded against intercurrent disease, and to be placed in good hygienic surroundings. The treatment, on the part of the physician, should be of the most careful and watchful character, should be adapted to the case, increased or diminished, as necessary, should be supplemented with tonics, and hematics, and blood-making food. He should enjoin upon his patient the utmost obedience as to mode of life and to taking of medicine. The truth is that syphilitics should place themselves under the care of a physician during the first two or three years of their disease continually, and they should be made to undergo a succession of treatments. They need not take medicine all of this time; there are, of course, intervals in which medicine or rather mercurials should be stopped, and in which, perhaps, tonics should be given, so that the patient really would not be treated for more than a year or fourteen months, at least he would only take medicine during this period. It is fortunate that the popular prejudice against mercury is gradually dying out, and that we have less and less resistance from patients as to its use, for it is really upon this that their future health and happiness depend; no other medicine will replace it in early stages, and if it is not a specific it certainly is when carefully and properly administered an almost perfect cure.

It is a sign of great progress that our knowledge of the use of this precious drug is becoming so precise, and that we can accomplish so much with it, and I think we can truly and justly say that, under ordinary circumstances, it will rid syphilis of its dangers and terrors. It is gratifying to think that the really learned men in syphilology prize this remedy so highly, and report such results from its use. When we hear the ill-natured, illogical, and often abusively coarse arguments of the few against it, we take pleasure in thinking that their numbers grow less yearly, and that their position in science does not warrant their vehement and positive declarations. Again, as an adjutant, we have that inestimable remedy, the iodide of potassium, which towards the latter part of the course of treatment, either alone or in combination with mercury, finishes the cure already begun. The practical application of these facts to your ends, Mr. Editor, is this:

During the first two or three years of the existence of syphilis in a patient there are really no absolute signs by which you may assure yourself that he will not succumb to some manifestation of the disease. If, however, he, during that whole period, is actively and properly treated by a skilful physician, even if his disease is severe, if at the end of that time he has not within six months or a year shown any syphilitic lesion and then appears to be in good health, if the ganglia of the body have, as they generally do under this treatment, subsided to their normal or nearly to their normal size, I think you can take such a man as a very fair risk. The key-note to the whole matter is the treatment—I would say the prolonged treatment—and it is my firm conviction, based on very careful and I hope I may say without arrogance quite extended observation, for syphilitic patients should be watched with much care and solicitude, that if they would place themselves implicitly in the care of their physician during those critical two or three years (providing of course that he is not an antimercurealist and that he is of a regular school of medicine) and would follow out sedulously the treatment directed for them, that in a very few years we should cease entirely to see examples of tertiary lesions, and the health of the coming generations would be modified in a marked manner for the better. If we can only impress syphilistics with the fact of the critical nature and importance of their condition during the first two or three years of their infection, we can soon make a very perceptible decrease in the mortality lists of this disease and of its concomitants. I must here impress upon you clearly the fact that a syphilitic person, even if previously healthy, who has not been treated thoroughly and persistently during the early years of the syphilis, is not a good and safe risk, notwithstanding that he may not recently have presented lesions and that his disease may have been mild. It is true he appears healthy and that he shows no evidence of morbid condition, yet we know that he has been the victim of a proliferative disease which has not in the proper stage been properly modified, hence we are not sure that some infiltration may not form and that life will not be compromised. You know that the beneficial action of mercury consists, essentially—and this certainly is a reasonable explanation—in the destruction by inducing fatty change of the neoplasms of syphilis and of rendering them ready for elimination. These new heterologous cells which syphilis causes undergo multiplication into infinite quantities, and besides this their presence in the tissues induces a tendency in such to almost boundless proliferation. In the early stages of syphilis the tendency to proliferation is not alarmingly great, but if the condition is not

checked, it goes on, and it then becomes firmly fixed in the economy. In early years the proliferations may be broken up and the tendency thereto uprooted; but if the disease becomes in a chronic manner engrafted upon the tissues, there is a doubt whether an absolutely perfect cure can be obtained. Now, although I think that this early commenced treatment is almost an essential, yet if not delayed too long in the course of syphilis it will also be advantageous. I think you would be prudent in very cautiously dealing with a person who early in syphilis had not been treated or had been treated in an indifferent manner, and who had experienced a somewhat persistent if not even severe course of the disease. Certainly before such a person should be accepted, he should be made to undergo a quite lengthy mercurial treatment, perhaps combined with the iodide of potassium. Thus cell infiltrations are quite thoroughly removed. I think that relapses of syphilitic lesions, particularly of proliferations, are induced by these cells having remained and then from time to time undergoing copious fission. If they are early removed by the mercury they do not engraft a tendency to similar future changes, hence we have no relapses; but if they are left undisturbed to lurk in the tissues, perhaps in the glands, they from time to time, as it were, reinfect the system and induce tendencies to subsequent reinfections. The hyperæmiæ produced by syphilis are also severe in character; they depend in a measure upon the cell proliferations, but they are susceptible of cure by the remedies named. It is readily seen, then, that the danger in syphilis, in the otherwise healthy subject particularly, consists essentially in these proliferative actions and tendencies which are averted or stopped by early, active, prolonged treatment, whereas, if delay occurs, there is a morbid condition towards abnormal cell proliferation induced which may be attended with fatal accidents. Fortunately, even late, we can break up, and I think absolutely cure, this chronic state or tendency, we certainly can in most cases by prolonged treatment judiciously administered. But it is well to caution you against cases which have been neglected in early stages, and though they may be worthy of acceptance it is necessary to look at them critically. I think that in general, if the health of a person is, and has been good, if his syphilis has run a mild course, even if untreated at first, if he or she later on undergo a somewhat prolonged treatment, the subject may be accepted provided there are not any contrary indications. To put it practically, a man was infected five years ago, was and has been healthy, but has not been treated, or but indifferently; his syphilis has been somewhat active, though not manifested by lesion within a year: Is such a man a good risk? Generally it may be said that he is, yet the cautious examiner, aware of what even such an apparently healthy man may undergo in consequence of his untreated syphilis, hesitates, and although he does not refuse him he causes him to undergo a period of probation. These, Mr. Editor, are the main guides for you in the case of a man who was healthy before he became syphilitic; that you assure yourself that he was treated early, actively and persistently; that it is evident from facts that his disease has been favorably modified, and that as his present condition is good, it is fair to assume that his future health will be uninfluenced by his previous disease. I think that it will be conceded that prognostications based upon this lengthened experience and observation can be more positively made and are more to be relied upon than if they are drawn from deductions as to the course of individual

symptoms or lesions. Let us now see how the disease affects those of weak build, and those who have some constitutional dyscrasia or debility.

I approach the subject of the influence of syphilis upon persons of the scrofulous or tuberculous diathesis with some hesitation. The truth is that upon this portion of my subject I am confined to practical general conclusions, rather than to clearly and accurately stated pathological facts. As our knowledge of both the tubercular and scrofulous diatheses (if we admit a distinction) is not precise and well defined, it is of course impossible to trace step by step the relation of syphilis to them. I shall endeavor, however, to show that there are certain persons whose organism is of such a nature that in them syphilis is more than in others to be feared. We will divide these subjects into two classes: first, those who show a tendency to abnormal tissue proliferation; second, those whose general health is below the average, and in whom pulmonary affections are readily excited.

The first class of persons are examples of what we term scrofula. It is necessary, however, that I should more fully explain the condition. The state of the system with which they are affected may be either inherited or acquired, and the subjects thereof usually show well-marked signs of it, or at least it can be ascertained by careful examination. Such persons are of delicate fibre, pale and flabby. Their nutrition is not well performed, and they are weak and sickly. In them there is a tendency to subacute hyperplasia of organs and tissues, and congestions are readily excited. The ganglia become swollen under slight irritation, or perhaps are in such a state continuously. Inflammations in such subjects are readily caused, and they run a severe course. Pus is secreted in great quantities, and ulcerations in such persons are liable to be severe and extensive, or to run a subacute course. There may be no symptoms indicative of pulmonary trouble in such subjects, but their lungs are very quickly involved. This condition is what we here recognize as scrofula, and it can be readily inferred that it is not a favorable one combined with syphilis. Knowing as we do the decided tendency of syphilis to induce hyperæmia and hyperplasia, we can readily see that in the system of such a person every factor is favorable to the full development of the disease. In such subjects we may observe that the disease rapidly induces a cachexia which may prove fatal; it may cause or superinduce a visceral lesion, or several of them, followed eventually with death, or it may so powerfully modify any latent morbid predisposition for the worse, that the victim is carried off. In such subjects, pulmonary affections may be caused by the syphilis, without previous structural predisposition, or again it may, if such exist, even in a mild form, exert a malign and specific influence upon it, which is beyond the control of medication. Such subjects as these, if syphilitic, are bad, and as risks are almost unacceptable; however, something can be said in a hopeful manner of their future under careful treatment, assisted by auspicious surroundings. Such subjects even may pass safely through the ordeal of the disease. As to the course of syphilis in them, it may be said that the danger is most serious during the early years of its evolution. If they pass through, we may say on the average the first three or four years of their syphilis without complication, and at the end of that time, the treatment having been active and appropriate, if they seem healthy, it may be assumed with good reason that they are tolerably good risks. Care must always be exercised in the examination of such persons.

Turning our attention now to the second class, we are here met with obstacles. It is so difficult to determine with precision both what the tubercular diathesis is, and what persons may present it later on, that I am forced to speak with caution. In practice the best course to pursue is to inquire carefully into the family history, antecedents, and present condition of the patient, and from the data obtained to draw as near as possible correct conclusions. Syphilitics who have descended from a family in which pulmonary troubles have been frequent, particularly if their parents, or brothers and sisters, have given evidence of such diseases in an acute form, are to be looked upon with great suspicion. If the patient himself gives evidence of frequently recurring, even though mild, affections of the chest, it is fair to assume that his syphilis may enter largely as a complicating condition into their course. If there is, however, structural trouble in the lung, and if the patient is also syphilitic, he should not be accepted almost under any circumstances, certainly not until a considerable length of time has elapsed, during which he undergoes treatment. It is possible that a restoration to health may be produced, but this should not be assumed as being permanent, until some years have elapsed from the date of contagion. In these subjects the crisis may be expected early, let us say within the first few years, and that if they pass through that period without complications having arisen, it is certainly a circumstance of favorable omen. To sum up, I may say that all persons who have a pulmonary weakness are bad subjects for an attack of syphilis, and as risks for insurance should not be accepted until they give full assurance that they have passed the crisis safely. Too much caution cannot be exercised in dealing with such parties.

As syphilis manifests itself in such varied conditions, and attacks so many organs and tissues, it certainly is fair to assume that any part of the economy which has been impaired in its structure or function would be more liable than another to be affected by it. Again, as it awakens latent morbid tendencies, it is liable to complicate them in a serious manner. I have endeavored to arrive at some formula of statement by which I could point out the subjects most liable to syphilitic affections of the nervous system. These latter are often followed by death, consequently it is important to determine, if possible, who are to be the probable victims. We know that cerebral troubles in general, as well as neuroses, are in a measure hereditary, and from our knowledge of the action of syphilis, it is fair to suppose that such an hereditary condition might be powerfully complicated. Therefore if a patient who has shown any such tendency, or who has acquired any nervous or cerebral affection, becomes syphilitic, it is certainly judicious to suspect that he may have syphilitic complications. Owing to the formidable character of these, and of the dangers with which they threaten life, such subjects should not be hastily accepted as risks, even though they may give no evidence of any present or impending trouble. This is all that science will warrant me in saying in advance. As to the ulterior development of syphilitic nervous affections in healthy persons, I have simply to repeat what I have said about the chances of such in general, that if they are properly treated early in the disease, and if during that period they do not give evidence of any implication of the nervous system, they may thereafter be assumed to have an immunity to such, at any rate in the majority of cases.

It would be improper to pass unnoticed the rheumatic condition, hereditary and acquired, in its rela-

tion to syphilis. The latter disease certainly very often does stamp its morbid impress upon the former. In very many cases life is not compromised; still, in a large number of cases of severe rheumatic condition of the body, syphilis has run a severe course. I have often observed it to intensify the sufferings of such patients, to induce in them a condition of mal-assimilation, by which they become very weak, debilitated, and thin. Space does not permit me to consider this interesting subject as fully as I wish, therefore I pass it over in the general way of mentioning it. The practical point I want to bring out is this, that the combined rheumatic condition and syphilitic diathesis is often a formidable one, even to the extent of compromising life. Such subjects should be watched carefully, and only accepted after the lapse of a number of years, in which, under treatment, they have been apparently cured. If a syphilitic, early in his disease, presents himself with a general weakened condition due to chronic rheumatism, he should not be accepted.

Syphilis influences the two sexes somewhat differently. The female is in general much more profoundly affected than is the male, and, owing to various reasons, is often seriously impressed by it. Though many women experience a very mild course of the disease, I think it will be conceded that the number of those whose ordeal is very severe is much greater than is that of men. However, all things being equal, if they pass through the first few years well, and are carefully treated, we may accord to them the same cheering prognosis which we have found we were warranted in giving to the male.

I need not dwell upon the severity of syphilis in the negro and in mixed races, but shall content myself by stating the fact that they are not in general good risks.

This, Mr. Editor, is, I believe, a comprehensive but not exhaustive review of the subject suggested by you for consideration, and I trust that I have been able to bring out true facts and to have stated them in an intelligible manner.

125 E. 12TH ST., April 12, 1875.

OTORRHOEA AS A CAUSE OF REJECTION.

By ALBERT H. BUCK, M.D.

THE question is often asked, "What value should the medical director of a life insurance company attach to the circumstance that an applicant is afflicted with a chronic purulent discharge from the ear?" Should a sweeping rule be laid down that all such applicants are to be rejected, or only accepted for short endowments,—a practice which prevails, I am told, among the best English companies,—or should these cases be investigated and the decision made to depend upon the result of the investigation? The sweeping rule is, of course, the safest and simplest. At the same time such a course would lead to the rejection of many good risks, which other companies would probably be quick to accept.

The reason why this class of risks is looked upon as undesirable is this:—these individuals, besides having to run the same chances of death from disease and accident which other men must run, are afflicted with a local inflammation in very close proximity to the brain, an inflammation which may at any time excite a fatal meningitis, or, by involving the veins of the neighborhood, lead ultimately to an embolism of some important arterial twig, or to the equally serious condition of septicæmia or pyæmia. Some, while fully recognizing this danger, may ask the question,

Is it not possible to discriminate between these risks, and to separate those, in which the danger is but slight, from those in which it is more threatening? To a certain extent this might be done. A person accustomed to examine the ear could, by an examination, select without any difficulty those cases in which the danger was so slight as not to impair the quality of the risk. Cases of ear trouble, however, come up so rarely for consideration, that most companies would prefer to adopt the sweeping rule of rejection rather than incur the expense and delay of a special examination. On the other hand, there is no doubt but that a few questions properly answered will generally enable the medical director to ascertain which of these risks it is best for the company to reject. I would suggest the following as suited to elicit the desired information:—

How long have you been troubled with a discharge from the ear?

Is it constant, or does it sometimes stop for a time?

Is it thick or watery in character?

Has it an offensive odor?

Is it ever tinged with blood?

Are you subject to pain in the affected ear, or to pain in any part of the head? If so, state full particulars.

Does pressure behind, above, or in front of the ear cause pain?

If, in answer to these questions, it is stated that the discharge is neither bloody nor specially offensive, and that it is not an abundant discharge; that it is never accompanied with pain or "headache;" and that pressure in the vicinity of the ear does not cause pain, the risk may fairly be considered—other things being satisfactory—as not an extra-hazardous one.

Miscellaneous.

THE AGE OF SUICIDE.—The influence of age upon suicide is a study of more than speculative interest, on account of its practical bearings and of the ease and precision with which it can be demonstrated. By age is meant the critical periods of life. These periods having many components besides the mere fact of years, it is apparent that what we have to examine is a many-sided phenomenon, including together with it the advance in life, the workings of physiological, mental, and sociological causes. It has been lately examined by Dr. O'Dea, and it appears that the maximum of suicides of both sexes occurs between the ages of twenty-five and fifty-five. Previous to the twenty-fifth year there is a sudden increase from two suicides between the ages of five and ten, to 136 between twenty and fifty-five. After fifty-five the tendency to suicide declines, but more gradually than it rose, except at sixty-five, where the number increases from 81 to 83—a rise so slight, however, as to be little worth considering. There are, therefore, three suicidal periods in life: those of organic and mental growth, of organic and mental completion, and of organic and mental decline. In the first the chart shows 80; in the second, 942, and in the third, 311. Comparing the periods in round numbers, it may be said that they are as one for childhood and adolescence to twelve for adult life, and to four for the years of bodily and mental decay. The influence of sex and its attendant circumstances upon suicides at the different periods of life is shown upon the charts. With females, as among males, there is a sudden and abrupt rise until the twenty-fifth year is reached. This rise is continued to the thirty-fifth year,

at which the maximum of suicides occur among women. The period from the twenty-fifth to the thirty-fifth year corresponds to that of the greatest pressure from domestic troubles and responsibilities, and also with the greatest activity of the maternal functions. The line thence descends abruptly to the forty-fifth year, whence it rises to the fiftieth, the critical period of mature female life, and then goes down, down, until it reaches the level from which it started. There are, therefore, two culminating points, and while the line on the male chart is undulating and sustained, that on the female chart is vertical and abrupt. The lower of the male culminating points is the higher of the female, and, contrariwise, the lower of the female is the higher of the male. These charts do not show the relative frequency of suicides among the two sexes. The ratio of suicides to population in the United States is (for the period covered by the last decennial census) 25 to 100,000 among males, and 3 to 100,000 among females. The only periods at which suicides are nearly equal for both sexes is from fifteen to twenty years, during which the number of boy suicides was 34, of girl suicides 32. After this the number of suicides among males is much greater than among females.—*London Med. Record.*

FEMALE MORTALITY.—Mr. A. Smece, F.R.S., fully understood from the paper which had been read, and which accorded with what they thoroughly ought to know, that female lives as a whole were rather better than male lives. How came it, then, that every practical man engaged in insurance was very much afraid of female lives, and would never like to hold any very large number of them in his office? As far as he had looked into this question, the answer was perfectly simple. It was that the female between 16 and 45 was exposed to the risk of childbirth. That risk might be likened to a sword suspended by a slender thread over every woman's head. If the string broke and the sword descended upon her, she had a very great risk of losing her life from the event. It was very well to say that women were better in the duration of their lives from 20 to 70 years of age. That might be true; but it was also true that if they took a number of females in the child-bearing period they would find that the mortality which occurred to them was very different from that which occurred to females who did not give birth to children, and very different from the mortality of males. It would be found that in this country the greatest number of children were born when the mothers were about 25 years of age. He thought that it would be found that at about the age of 25 years the greatest number of deaths occurred among women year by year, relatively to the number among males. Speaking from memory, he believed that the deaths in the 25th year were about 75 per cent. more among married women than among unmarried women or men. That 75 per cent. of deaths diminished year by year until they had crossed the line of about 47 years. At 47 the number that died was identically the same among women as among men. After 47 the female character for longevity again came into play, and women bore a pre-eminence in that respect over men for the rest of life. If actuaries looked at that simple enunciation of the fact they would find that a great deal of the difficulty with which they had to deal lay in the premature deaths of females in the parturient period between 20 and 47. There would be no difficulty if, when a female made a proposal for insurance, she was compelled to pay a premium for the rest of life. She, however, got over her time of danger and then ceased pay-

ment. He had seen the proposal made—but very seldom taken—for a woman to insure her life for a one-third credit premium, the premiums payable quarterly, so that after she had passed her risk she could drop her insurance. That was the danger from which insurance companies suffered, and about which practical men had to be careful. They must take care that a woman did not come into the society during the time she was exposed to risk, and go out as soon as the risk had passed away. He believed that that was the whole story of the danger of the insurance of females. He gave a little weight, and but a very little, to the assurance of a woman by her husband who knew that there was some defect about her. But every one must know that such cases were sometimes insured. Another point which had been raised in the paper was whether the examination of females was as perfect as that of males. Unquestionably the medical men must use more delicacy, and if a woman came before them they must not disgust her by such questions or such treatment as would cause her to go away. He remembered seeing on one set of papers the question gravely asked of the medical man, "Have you palpated her abdomen?" He need hardly say that that was an operation which no medical man who had any respect for delicacy would like to practise in such an examination. He, therefore, thought that their estimate of female lives was a little worse than that of male lives. Moreover, women had a greater faculty of concealment than men. If a medical man asked them a question they would sometimes exercise a very happy knack of saying "no" when they ought to say "yes;" and they would altogether forget slight occurrences, which they might think quite immaterial, but for which a medical man would reject the proposal. All these things were very simple, and he thought that any medical man of skill taking them into consideration might work the assurance of a number of females so that they should be as good as males, barring the pregnancy and its consequences. That risk occurred over a series of years at irregular intervals, and offices ought always so to protect themselves that women should never have the benefit of the insurance during the time of peril, and throw it up during the time when their mortality was less.—*Remarks made before the London Institute of Actuaries.—From the Spectator.*

WEIGHT AND HEIGHT OF AMERICANS.—According to a recent work of Mr. B. A. Gould, Actuary to the United States Sanitary Commission, in which some very interesting figures relative to soldiers in the last war are given, it appears that the American nation, instead of being degenerate and inferior to the European race in point of physical perfection, is far the reverse. The figures adduced show that "the tallest men were from Michigan, Illinois, and Wisconsin; the next tallest, from New England, New York, New Jersey; and the shortest from Scotland, England, Germany." In weight, the men of Kentucky and Tennessee were the heaviest, averaging 150 pounds; England, Scotland, France, Belgium, all between 138 and 139 pounds. The ratio of weight to stature gave in pounds to the inch: Ohio and other Western States, 2.185; New England, 2.131; England and Scotland, 2.118; Germany, 2.168.—*Medical and Surgical Review.*

IRISH STATISTICS.—During the last quarter of the year, the birth rate in Ireland amounted to 24.4 in every 1,000, and the death rate to 17 per 1,000, the latter being somewhat beyond the average of preceding years, and the higher mortality being due to the prevalence of scarlatina, and to the inclement weather. —

Original Lecture.

THE GENERAL PHYSIOLOGY OF THE
MOVEMENTS IN THE BODY.

By J. W. S. ARNOLD, M.D.,

PROF. OF PHYSIOLOGY, UNIVERSITY MEDICAL COLLEGE, N. Y.

Photographically reported for THE MEDICAL RECORD.

LECTURE I.

GENTLEMEN: We shall this morning begin the subject of movements. The movements which are met with in the body may be divided into two classes—passive movements and active movements. Under the head of passive movements we simply refer to those which are produced, as I have already told you,* by the action of elastic tissues, especially by the yellow elastic fibrous tissue.

When a muscle contracts, acting upon certain parts of the body, motion is produced. When relaxation takes place, under certain circumstances, the return to the normal position is produced, in part at least, by the elasticity of the yellow fibrous tissue. This illustration gives us an idea of one class of movements which is observed in the body. On the other hand, active movements are produced by the contraction of muscles. There are two kinds of muscles that contract, viz., the voluntary and the involuntary. The movements produced by the contraction of involuntary muscles are slow and gradual; while those produced by the voluntary muscles are rapid and impulsive. The contraction of a voluntary muscle takes place upon the reception of a stimulus, and is followed by a relaxation; both contraction and relaxation being comparatively rapid. Whereas after stimulation has been applied to involuntary muscles, the contraction goes on slowly, after a time reaches its maximum, and relaxation follows in nearly the same manner. Examples of the action of involuntary muscles, are the peristaltic movements of the intestines, and contractions of the muscular fibres of the uterus during labor. Now, besides these, there is another group of movements which seem to be classified alone. These are movements seen in peculiar substances. First, there is the movement observed in *protoplasm*, or protoplasmic movement. Protoplasm we have already defined as a mass of living matter. Why do we say that it is living? Because it has the power of motion, and the power of taking to itself nutritive substances by which its existence is maintained. These protoplasmic masses are among the lowest orders of beings. In these beings we may observe a motion that is slow, slight to be sure, but which is for the purpose either of surrounding material for purposes of absorption, or for purposes of locomotion. If for example we examine a mass of protoplasm represented by a circle,† we shall find that the manner in which movements occur in this substance is as follows: At certain points little projections appear, termed pseudo-pods; and then these projecting portions are returned within the mass, so that the original circle is restored. The portions will project a little farther, a second time, and sometimes the form of the mass becomes changed from a spherical to an oblong shape. Now, if one portion becomes fixed, and the other portion is drawn into the substance of

the mass, so as to form a circle again, it is evident that there has been a movement from one point towards the other. This is what takes place in the wandering cells, or white blood-corpuscles, or leucocytes; these bodies being simply masses of granular protoplasm.

Besides this protoplasmic movement, we observe in the body movements which are seen in connection with *cilia*, upon ciliated epithelium. There are certain situations in which the movements of cilia may be observed. The form of the epithelium is conoidal, which you already well understand, and the cilia are the numerous hair-like appendages attached to the free or broad extremity. The pointed extremity of the epithelial body is attached to the basement membrane or submucous tissue upon which it rests. Now, during life and a certain length of time after death, there is a constant movement of these hair-like appendages, called ciliary movement, and this is always from within outward. If, therefore, we have a mucous membrane, like that which lines the respiratory passages, which is covered with ciliated epithelium, we may observe a continual movement over its surface from within outward.

In this way a considerable current is established, and the function, it is self-evident, is to prevent the entrance of certain substances into the deeper portions of the lung. The rapidity of these movements, of course, is not great, but a current can be observed that moves at the rate of from $\frac{1}{240}$ to $\frac{1}{175}$ of an inch in a second. This is the average of vibration in the cilia of the frog; but in the higher animals, where the cilia are more abundant, the movements are much more rapid. In the nasal and respiratory passages of man the movements are very much more rapid, and may reach as high as 350 vibrations per minute. How is this motion produced? I cannot tell you, for we do not know exactly how it takes place. It does not, however, depend upon any nervous agency. It seems rather to depend upon some inherent property possessed by the homogeneous substance of which the cilia are composed. Upon further examination it has been found that this ciliated movement is influenced by certain reagents; for if we subject the cilia to the action of acids, although of feeble strength, the movements cease at once; while if we subject them to the influence of alkalies, diluted, the movements for a certain time will be increased, but very soon after cease altogether. Again, these ciliary movements continue, although the animal may be in a condition of complete anaesthesia either by chloroform or ether. When, therefore, the nerves are deadened to all sensibility, these cilia continue to move, showing that they must possess some peculiar property which does not belong to other tissues. So far, gentlemen, we have only referred in a general way to the various kinds of motion observed in the body. There are, however, besides the motions which have been described as active and passive, certain phenomena which we have studied while upon the subjects of deglutition, circulation, etc. With reference to the circulation, the motion *seen* is almost entirely that produced by the elasticity of the arteries. In the arterial system a certain amount of motion is produced by the contraction of the involuntary muscular fibres of the arterioles. In connection with the motion of the heart, the movements are referred to the action of the striated muscle, because its movements are powerful and sudden.

When a muscle contracts there are certain phenomena which attend its action. In the first place, the red or striated variety of muscle possesses what is termed *elasticity*. In other words, if we hang upon a muscle a certain quantity of weight, it is found that it is ca-

* In a previous lecture.

† Diagram illustrating amoeboid movement.

pable of being extended or stretched, and then if the weight be removed, that it is capable of returning to its original length. This will take place provided the weight attached to the muscle be not too great. Take a piece of india-rubber and attach a given weight; it will be extended a certain distance; add double the weight, it will be stretched proportionately to a greater extent, or double the distance. But this does not hold good in the case of muscle, although both the india-rubber and muscle possess the property of elasticity. The muscle will be stretched a certain distance with a given weight, but after that, if the weight be increased, the elasticity gradually diminishes out of proportion to the weight. When we reach a certain point the muscle has no power to return to its original length, for we have passed the limit of its elasticity. This elasticity can be observed only during the life of the muscle. Kill the muscle by dipping it in warm water, and then add weights to it; the muscle can be extended, but when the weights are removed it has no power to return to its normal length.
